Atypical Growth, Abnormal Mitosis, Polyploidy and Chromosome Fragmentation Induced by Hexachlorocyclohexane

THE best insecticides and fungicides will be those which kill the plant parasites without affecting the plant organism. In fact, they all affect the host plant more or less in various ways and degrees[1–4]. A series of fungicides and insecticides may have very similar effects on the plant organisms. Ethylmercury-chloride (CH_3CH_2HgCl), which is the active substance (2 per cent) of the fungicide 'Granosan', induces atypical growth, abnormal mitosis and polyploidy[3,4], reminding one of the effect of colchicine and acenaphthene[5,6]. A similar and very strong effect of this kind is produced by hexachlorocyclohexane—another chlor-organic compound—which is the active substance of a series of very effective insecticides, recently recommended under various names. The insecticides 'Agrocides' (7, 3, etc.), for example, the active substance of which is the gamma isomer of 1,2,3,4,5,6-hexachlorocyclohexane ('Gammexane'), induce atypical growth, suppressing the development of the roots, stems and coleoptyles of gramineous plants, producing very striking thickening of these organs, especially of the growing points (root tips and coleoptyles).

Active insecticides, manufactured in various countries (hexachlorane, 666, etc.), and containing several isomers of hexachlorocyclohexane, including the gamma isomer, act in a similar though not in an identical way. Hexachlorane, for example, stimulates the germination of certain Cruciferæ (*Brassica nigra*) and other plant seeds during the first two days, so that they were even ahead in growth, when compared with the control samples, and much ahead when compared with the germinating seeds treated with 'Agrocide 7'. But soon after this, the controls grow on, while the growth of the treated seedlings becomes strikingly suppressed. We have treated with insecticides containing hexachlorocyclohexane the seedlings of the following plants: *Zea mays, Triticum vulgare, T. durum, T. monococcum, T. compactum, Secale cereale, Helianthus annuus, Crepis capillaris, Vicia faba, V. sativa, Brassica nigra*, etc.

The cytological studies of the affected root, stem and coleoptyle tissues show that these agents act first of all upon the cytoplasm and interfere with the cytoplasmic processes involved in the formation of achromatic figures. The chromosomes do not arrange themselves in an equatorial (metaphasal) plate after prophase, but remain scattered, as they are during the prophase. They appear less bent than usual. The thickening of the chromosomes, that is, the accumulation of nucleic acids (nucleoproteins) on the chromosomes and the reproduction and splitting of the chromosomes, proceeds, although the processes involved in the formation of achromatic figures are highly disturbed or even entirely inhibited. The chromosomes thus reproduce, but remain where they are, without moving toward the poles. In fact, poles are not formed. After such a reproduction, the chromatolytic (nucleoproteolytic) processes proceed and a nucleus is formed containing twice as many chromosomes as before the beginning of the abnormal mitotic processes. The main trend of the processes of chromosome doubling reminds one of those induced by colchicine, acenaphthene and other polyploidizing agents.

Since the insecticide continues to act further, the next abnormal mitosis ends with a second chromosome doubling and so on. Thus tetraploid and octoploid cells appear, and cells of a much higher degree of polyploidy. Alongside these, certain diploid cells that have not yet undergone the abnormal mitosis can still be found.

Chromosome multiplication leads to increase of the size and occasionally of the number of the nuclei, and further to increase of the size of the cells. Thus the cells grow instead of multiplying and differentiating, leading to swelling of the roots, stems and coleoptyles.

The solubility of hexachlorocyclohexane in water is very low, therefore it is applied as powder. Its effect is so striking that it can be used as a polyploidizing agent, especially when one considers the fact that it is much cheaper than other polyploidizing agents.

In certain cases a chromosome group or groups may move slightly in some direction or directions into the cytoplasm. Such a slight separation may occasionally end with formation of two, or more than two, aneuploid nuclei; thus polynucleate, or cells with monstrously deformed nuclei, appear. In certain cases cell wall is formed between such nuclei. This leads to formation of cells with aneuploid chromosome numbers. Dead cells were occasionally found in the roots, stems and in the coleoptyles. They may have been aneuploid. All these phenomena are due to the activity of the agent upon the cytoplasm.

But the active agent also induces certain changes in the nuclear elements, namely, in the chromosomes, no matter how rarely they may occur. Fragments of one chromatid or of a chromosome (both chromatids) were also observed, although very rarely.

Such insecticides or fungicides, when applied, may increase the hereditary changes in the cultivated varieties ('pure lines'), leading thus to more rapid degeneration of the highly bred uniform varieties. This means that when one applies such insecticides or fungicides, the seeds of the varieties being propagated should be changed more often, so as to provide new non-degenerated stocks.

Mutations Induced in *Coprinus fimetarius* (L.) by Nitrogen Mustard

DURING recent years, numerous experiments have been performed in order to induce mutations in various fungi belonging to the Ascomycetes group. Of special interest are the mutations affecting physiological characters in *Neurospora*[1] and *Ophiostoma*[2] produced by irradiation, mustard gas or nitrogen mustard. These investigations led me to perform similar experiments with a Basidiomycete, *Coprinus fimetarius*.

In the first experiments, basidiospores from sporophores formed in pure culture were subjected to ultra-violet radiation from a quartz lamp (Original, Hanau), plated out on malt agar, and the developing monosporous mycelia isolated and studied. Even after a very long irradiation, however, the treated spores possessed the same germination capacity as untreated ones, and no morphologically deviating mycelia were observed. Thus the irradiation did not seem to exert any mutagenic effect upon the spores. The surprising resistance might be due to the thick epispore of the *Coprinus* basidiospores, which probably absorbs the ultra-violet rays.

Treatment with nitrogen mustard ($(\mathrm{Cl.CH_2.CH_2})_2.\mathrm{N.CH_3}$), on the other hand, gave positive results. In the first of the two experiments with this compound, the spores were suspended in a 0·25 per cent solution of nitrogen mustard at *p*H 5·6. After 30 min. the treatment was broken off by diluting the suspension twenty-five times and plating out the spores on malt agar plates. The percentage germination was 2·4 per cent compared with 25 per cent in untreated spores. From the plates, 462 monosporous mycelia were transferred to flasks containing 5 ml. of a synthetic nutrient solution ('minimum solution') giving optimal growth for *C. fimetarius*, wild type[3].

Many of the spores treated with nitrogen mustard developed morphologically deviating mycelia; but only the physiologically deviating mycelia, however, were more closely studied. The mycelia which did not develop in the minimum solution were transferred to malt agar tubes and their specific requirements examined. Three physiological mutations (0·6 per cent) were found, two of which (Nos. 23 and 32) required hypoxanthine or adenine for growth; the third mutant (No. 17) requires an as yet unidentified amino-acid, or a combination of amino-acids.

In the second experiment, the spores were treated with 0·5 per cent nitrogen mustard. The percentage germination was 1·9 per cent (against 32 per cent in the control), and 454 mycelia were isolated. Two of them (Nos. 54 and 78) were mutants, both growing with methionine or cystein, and thus probably representing induced parathiotrophy (Volkonsky[4]).

In one case, No. 32 (hypoxanthine-less), the inheritance of the induced character was studied. *C. fimetarius* being a tetrapolar, heterothallic fungus[5], four test mycelia (Nos. 7, 3, 5 and 1) could be isolated representing the mating types a_1b_1, a_2b_2, a_1b_2 and a_2b_1, respectively. No. 32 conjugated with No. 7 (a_1b_1), and the dicaryotic mycelium formed was inoculated into a flask with sterile horse manure. Despite the fact that half the nuclei in the mycelium were hypoxanthine-less, several normally shaped sporophores developed in the flask in eleven days. Spores from them were plated out on malt agar, and 46 monosporous mycelia were isolated; 21 of them turned out to be hypoxanthine-less, the remaining 25 representing the wild type. The hypoxanthine-less mycelia were segregated into all the four mating groups, three mycelia representing a_1b_1, six a_2b_2, three a_1b_2 and nine a_2b_1. To judge from these figures no strong linkage seemed to exist between the mutated gene and the incompatibility factors, *a* and *b*.

A back-cross between No. (32 × 7)11, a_1b_1, and No. 32, a_2b_2, gave a completely hypoxanthine-less dicaryotic mycelium, which grew well on sterile manure but did not form any sporophores.

The hypoxanthine-less No. 32 (a_2b_2) and the parathiotrophic No. 54 (a_1b_1) conjugated and formed a dicaryotic mycelium capable of growing in the minimum medium just as well as the wild type. This mycelium obviously represents a case of 'intracellular symbiosis' analogous to the heterocaryotic mycelia of *Neurospora*[6], but probably differing from them in that the two sorts of nuclei always occur in equal numbers, because of the conjugate divisions. Sporophores were formed on sterile manure, but no spores have as yet been obtained.

Some Stereochemical Aspects in Genetics

It is a fundamental concept in modern chemical genetics that a separate gene is responsible for each step in the enzymatic biosynthesis of a given compound. Since *in vitro* the precursor (or precursors) of the compound would also be able to produce substances other than that formed in the tissue, a gene, as is well known, displays a chemical steering power which is directed toward a single structural target.

We suggest that in the evaluation of the degree of selectivity in this steering function of some genes, one has to go further than usual by thinking in stereochemical rather than in purely chemical terms. In the case of those carbon compounds which are able to assume two or more *cis-trans* forms, their biosynthesis can be effectively steered in the tissue towards a single spatial model. This can be demonstrated in the field of the carotenoids, which are produced annually on the hundred-million-ton scale in the vegetable kingdom. In the overwhelming majority of the plants, only the all-*trans* configuration appears. For example, during the biosynthesis of lycopene in the ripening of ordinary tomatoes, this particular configuration is selected out of the seventy-two stereochemical possibilities, and none of the other seventy-one stereoisomers can be found in fresh extracts by careful adsorption analysis.

That a stereochemical steering factor must be made responsible for this spatial selection and not an excessive lability of all *cis-trans* isomers neglected *in vivo* follows from the appearance, in exceptional cases, of such poly*cis* forms of lycopene, which can be crystallized easily and show a degree of thermostability similar to that of the all-*trans* compound. The first such reported case was the occurrence of 'prolycopene' in the 'tangerine' variety of tomatoes[1].

There are three genetically different flesh colours known in tomatoes: yellow, orange and red. The yellow fruits carry the recessive form, *r*, of the basic gene for lycopene formation. Both the orange and red fruits possess the dominant gene, *R*. In addition, however, the orange-coloured tomatoes, which contain the poly*cis* compound, prolycopene (besides other *cis* lycopenes), is recessive in the gene *t*; and the red fruit which exclusively produces the all-*trans* form of lycopene has dominant *T*. Whereas the biosynthesis of either all-*trans*-lycopene or prolycopene requires the dominant gene, *R*, the gene pair *T* and *t* determines the spatial configuration of the lycopene molecule[1].

We expect that other instances may be found in which one gene is responsible for the building up of the chemical structure proper of a compound, and another gene steers the molecules thus formed into a predetermined stereochemical configuration.

A spatial difference (*cis* or *trans*) around a double bond does not modify only a detail in the polyene molecule but also, as models show, it profoundly changes its overall shape[2]. While an all-*trans*-lycopene molecule has a rod-like form, this becomes a V-like pattern when a centrally located double bond assumes *cis* configuration. Again, when several more such rearrangements take place around other double bonds, the molecule straightens out.

Of course, not each of the sterically possible geometrical forms of a given compound can fit equally into a biological system. Hence, it is an important function of some special genes to secure the most suitable spatial configuration; however, if a compound is not subject to stereoisomerism, its genetics can be satisfactorily treated in terms of two-dimensional structural chemistry.

While so far our discussion has referred to the morphology of single molecules of relative simplicity, some bio-processes which consist of arranging many building stones into high-molecular complex structures may also be considered on similar lines. One can conceive a difference between such genes the function of which is to link building units together, and others which arrange the biosynthetic end-product into a predetermined spatial pattern. The first type of genes, which are being studied with so much success, for example, in the case of *Neurospora*[3], determines the chemical composition of the tissue; but the second type is concerned with the organic form. It may also determine the spatial relationship of the constituents within a cell or the specific arrangement of molecules into some micro- and macroscopic structures. In this respect one should also consider genes which affect the symmetry of organisms. An interesting example is that of a freshwater snail in which the direction of coiling of the shell is genetically determined by a single gene-pair[4].

The original concept of the gene took into account both its effect on chemical composition and form. While important modern studies are stressing typical biochemical effects in genetics, recent stereochemical observations on some natural pigments may contribute to the emphasis on the three-dimensional form, that is, the genetically predetermined spatial shape of both simple molecules and complex organic structures.

Local Action of Calciferol and Vitamin A on Bone

IT has been shown[1] that if the parathyroid glands of young mice are attached to small, excised pieces of parietal bone, and the two grafted together to the cerebral hemisphere of a litter-mate, intense osteoclastic resorption of the bone in the immediate vicinity of the gland is demonstrable after 10–14 days. The same method has now been used to study the local action of calciferol, vitamin A and œstradiol on bone.

The small crystals of powdered calciferol were cemented together into lumps about 0·5 mm. in diameter with human fibrinogen and thrombin solutions, and these pellets were attached with the same medium, plus penicillin, to the centre of pieces of parietal bone 2–3 mm. square, cut from 10-day-old *C.57* black mice. The grafts were thrust vertically into the cerebral hemisphere of a litter-mate through a narrow hole made in the skull and were examined in saline after 10–14 days. Similar experiments were performed using cholesterol. In some cases the crystal-pellet could be seen after removal, and its position correlated with the structure of the adjacent bone as revealed in the dry specimens after maceration in potash. In other cases the pellet was displaced or detached in removal. The three 14-day calciferol grafts (Fig. 2) all showed very definite resorption in the central region, corresponding closely to the site of the crystals, and in two of them the bone was perforated. The five 10-day grafts also showed definite, but less pronounced, erosion. In all specimens resorption was irregular and appeared to involve the widening of pre-existing spaces and foramina over a fairly large area. The cholesterol grafts (Fig. 1), in contrast, showed no evidence of local resorption, the bone surface being smooth and dense, and with a certain amount of irregular thickening, particularly at the periphery; previous experience shows this to be common in all types of grafts with parietal bone, even if no crystals are attached. The experiments strongly support McClean's[2] suggestion that the osteoporosis which results from massive doses of calciferol is due, at least in part, to a local action of the vitamin on the bones.

Six grafts performed with single small chips of crystalline vitamin A acetate showed intense and more sharply localized resorption after 14 days. Four of them (Fig. 3) were perforated by a large hole, at the sharp edges of which osteoclasts could be seen after supravital staining with neutral-red in the manner I have described[3] previously. Two others showed a concave depression formed of thin bone, with minute perforations in some regions of it. Neutral-red staining revealed approximately 150 osteoclasts spread over each of these concavities, which are apparently due, as in parathyroid grafts, to new bone formation on one surface keeping pace with resorption on the other. The sharpness of the perforation as compared with calciferol grafts may be due to the use of a single fragment, which was therefore not interpenetrated by fibrin. It is very unlikely that the effect is due to mechanical pressure, since

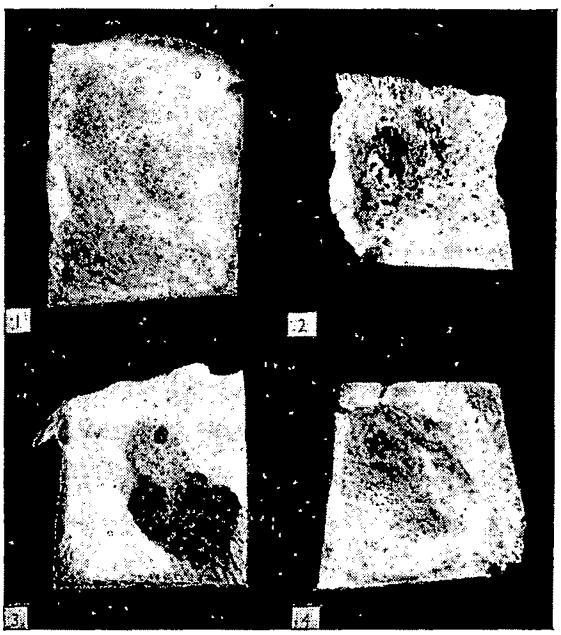

Fig. 1. Cholesterol graft. Fig. 2. Calciferol graft.
Fig. 3. Vitamin A graft. Fig. 4. Vitamin A graft.

fragments of glass did not produce resorption, and in one specimen the glass became closely embedded in the bone surface without perforating it. The local reaction of the bone to the pressure of a grafted fragment may, of course, be modified if the fragment also exerts a physiological effect by virtue of its chemical character. Grafts performed with carotene, made up in fibrinogen–thrombin clot, showed no resorption or other noteworthy effect. It appears that the fractures observed by Moore and Wang[4] and others in rats given massive doses of vitamin A may be attributable to local action on the bones, and the results are interesting in relation to Mellanby's[5] findings on the effect of vitamin A deficiency on osteoclasis. As might be expected, carotene is evidently not converted to vitamin A by bone tissue, at least to any considerable extent.

Ten grafts (five into male and five into female hosts), using small single chips from a fused œstradiol tablet, showed no evidence of either local resorption or increased local bone deposition. Increased deposition might, perhaps, have been anticipated in view of the known action of injected œstrogens in promoting bone-formation in the medullary cavities of the long bones. Sutro[6] claims that osteosclerosis of the calvarium also occurs in young mice of either sex given prolonged œstrogen treatment. The character and degree of the response to œstrogens apparently varies in different regions of the skeleton: thus the pubic bone undergoes resorption; in the long bones only endosteal bone formation occurs; and the magnitude of the effect depends on dose – time relations. Further graft experiments, taking these factors into account, will be needed before the local action of œstrogens can be satisfactorily assessed.

The detailed results, including histological findings, will be reported elsewhere at a later date.

I wish to thank Prof. Daryll Forde for allowing me to complete the work while attached to his Department, Mr. F. J. Pittock for taking the photographs, and Miss I. Slowgrove for technical assistance. I am also indebted to Dr. W. F. J. Cuthbertson, of Glaxo Laboratories, Dr. S. P. Datta, Dr. Gordon Kennedy and Sir Edward Mellanby for the pure compounds used in this work.

Effect of Pantothenic Acid on the Infection of *Trypanosoma evansi* in Rats

WITHHOLDING of pantothenic acid from the diet has been shown by Becker, Mansera and Johnson[1] to interfere with the production of ablastin, the trypanosome-reproduction inhibiting antibody, formed by rats infected with *Trypanosoma lewisi*. An investigation of exploratory nature was undertaken to ascertain if pantothenic acid had a similar effect on the course of *T. evansi* infection in rats.

Experiment 1. Six rats, all kept on bread and milk, were used in this experiment. The diet of three of these was supplemented by pantothenic acid at the rate of 200 mgm. a rat daily for five days prior to infection and continued until the end. All the rats were infected on the same day with 3,000 trypanosomes each by the subcutaneous route. On the fifth day after infection, two out of three rats of the control batch showed trypanosomes in their peripheral circulation, while all three of the acid group remained negative. On the sixth day, only two rats of the acid group showed trypanosomes in the tail blood, while the third remained negative; in all the controls the parasites were swarming in the blood, and one died during that night. On the seventh day one rat of the acid group died, while two others had a rise in the number of parasites; controls showed an even greater number and died during the night; the remaining two of the acid group, on the other hand, died twenty-four hours later.

Experiment 2. The dietary and other conditions were the same as above; but the dose of the trypanosomes was increased to 46,000 a rat. The rats of both groups became positive on the third day; but the number of parasites in the controls was appreciably larger than those receiving pantothenic acid. One control rat died on the fourth day and the remaining two during the night; in the acid group, on the other hand, all three showed swarming parasites on the fourth day, survived the fifth day and died during the night.

Experiment 3. The conditions were slightly varied. A batch of ten rats was kept for fifteen days on a vitamin-free diet consisting of casein (vitamin-free), 20 parts; coco-nut oil, 5 parts; dextrinized starch, 71 parts; salt mixture (Osborn and Mendel), 4 parts. Five of these, in addition, received pantothenic acid as above. On the sixteenth day the rats received a dose of 2,500 trypanosomes each subcutaneously. In the control batch two rats were positive on the fifth day and all on the sixth day; while in the acid group one became positive on the sixth day, and with an addition of one on each day to the positive group, all were positive by the tenth day. Commencing from the night of the tenth day, all the controls died within the next forty-eight hours; whereas in the acid group the first death occurred on the twelfth day and within the next forty hours all were dead.

Though further experimental observations have yet to be made before any generalization can be attempted on the subject, the results presented here are interesting enough to merit publication. The results perhaps justify a tentative suggestion that pantothenic acid exerts an influence on the rate of multiplication of *T. evansi* in rats, although finally the host is overwhelmed by parasitæmia.

Bovines in India are considered to be 'carriers' of *T. evansi*, and the pantothenic acid reserve in these animals may play the important part of maintaining the 'carrier' condition. Sporadic fatal outbreaks of surra in bovines are, however, not uncommon in India, and the cause for this may perhaps be found to be correlated with the interference of pantothenic acid balance in these animals.

Our thanks are due to Dr. N. D. Kehar and Dr. N. B. Das for their help in these experiments.

Role of the Inorganic Constituents of Wheat Bran Extract in Streptomycin Production

WHEAT bran has been frequently used as an ingredient in media for culturing micro-organisms. Good results have been recorded from this laboratory for penicillin production by *P. notatum*[1] and streptomycin formation by *S. griseus*[2]. Detailed systematic investigations carried out to discover the factors in wheat bran extract responsible for these results have shown that the ash of the extract is mainly concerned so far as streptomycin is concerned.

Streptomycin fermentations were conducted in a manner described previously[3]. Streptomycin titre and the reaction of the culture fluids were studied daily. Antibiotic activity was determined from a standard curve obtained by the cup plate method. The following media were used:

I. Aqueous extract of wheat bran with total solids adjusted to 2 gm. per 100 ml.; pre-adjusted to *p*H 6·8.

II. 'Difco' peptone, 0·5 gm.; glucose, 1·0 gm.; sodium chloride, 0·5 gm.; distilled water, to 100 ml.; pre-adjusted to *p*H 6·5–7.

The inoculum consisted of a spore suspension of a Waksman's strain of *S. griseus*. The ash of the wheat bran extract was obtained by heating the total solids in an electric furnace at a temperature of about 1,000° C. for 10–14 hours. No attempt was made to dissolve the ash before adding it to the medium.

The accompanying table shows that addition of the ash at 500 mgm. per 100 ml. to medium II increased the streptomycin production to practically the same as that when *S. griseus* was grown in medium I. The ash content of medium I is 453 mgm. per 100 c.c.

Effect of wheat bran extract ash on streptomycin formation

Medium	Ash in medium (mgm./ 100 c.c.)	Reaction of medium (days)						Streptomycin in μgm. per ml.					
		4	5	6	7	8	9	4	5	6	7	8	9
I	Nil	7·1	7·2	7·6	7·7	7·9	7·9	69	111	114	109	92	91
II	Nil	6·9	7·4	7·4	7·5	7·6	7·6	24	24	25	28	24	24
	100 mgm.	7·1	7·2	7·3	7·4	7·6	7·9	24	28	36	64	64	48
	200 ,,	7·3	7·3	7·4	7·6	7·8	7·9	22	28	45	78	76	78
	400 ,,	7·4	7·5	7·6	7·8	7·9	7·9	28	28	54	98	85	88
	500 ,,	7·5	7·6	7·8	7·9	7·9	7·9	25	28	61	108	93	92

A similar observation regarding the role of inorganic constituents of corn-steep liquor in penicillin formation has been recorded[4]. Recently fatty acid-like components have been isolated[5] from solid wheat bran, and it has been suggested that these might explain the good antibiotic production by micro-organisms in wheat bran. Neither the aqueous extract of wheat bran used by us nor its petrol-soluble fraction has shown any antibacterial activity. The data presented above suggest that the good yields obtained by using the bran or its aqueous extract is independent of any influence likely to result from the antibacterial activity of the fatty acid component of the bran. Further work regarding the role of the different elements present in the ash is in progress.

My thanks are due to Dr. K. M. Pandalai for his suggestions, to Prof. V. Subrahmanyan for his interest, and to Merck and Co., Rahway, N.J. I acknowledge the financial support from the Council for Scientific and Industrial Research, India.

Vascular Wilt Disease of Oil Palms in Nigeria

IN 1946, I observed and diagnosed a vascular wilt disease of oil palms (*Elæis guineensis*) in the Belgian Congo, a strain of *Fusarium oxysporum* being consistently associated with the necrosed wood vessels[1,2]. An investigation in 1947 of diseased oil palms in various Nigerian plantations by Messrs. S. de Blank and F. Ferguson, of the United Africa Co., led them to the conclusion (private report) that vascular wilt disease was also present in Nigeria. Cultures which they submitted to me for identification consisted of strains of *F. oxysporum* very similar to those which I obtained in the Belgian Congo. During the present year, in an inspection of oil palm plantations in Nigeria, I obtained full confirmation of the presence of vascular wilt disease. Some plantation areas show how severe this disease can be, many 8–12 years old palms being killed off, together with the younger replacements. An important addition to our knowledge is that infected vascular strands can be observed in seedlings 18–24 months old: from these, *Fusarium oxysporum* and other species of *Fusarium* have been isolated. This fact may materially shorten the programme of breeding resistant varieties.

In Nigeria, as in the Belgian Congo, a leaf disease known as patch yellow has also an associated strain of *Fusarium oxysporum*, this strain being different from that isolated from necrosed vascular strands[2].

These observations give me an opportunity of saying that, broadly speaking, the major plantation problems are common to the whole oil palm region of West and Central Africa. Accordingly, it is to be hoped that the closest co-operation will be maintained by all bodies interested in the welfare of this important industry.

Bacteriophage Typing of Untypable *Salmonella typhi* Organisms

STRAINS of *S. typhi* reported as being untypable by bacteriophage figure largely in previous reports and vary between 30 and 8 per cent of the total[1].

Using a modification of the method described by Craigie for typing, the group of untypables can be divided into three more or less distinct sub-groups. The first is characterized by all specimens from the same source of infection giving a standard pattern throughout with certain Type II bacteriophages. This pattern reaction identifies the close relationship of the strains to one focus, but does not allow the strains to be classified into any one of the recognized twenty-four groups. The second subgroup, and the larger in my series, are strains which give no reaction with Type II 'phages, but react to pooled Types I and IV 'phages with clear, complete, confluent lysis. These types may easily be considered to be new types; but with the technique to be described, most can be classified into the existing ones. The third group are those in which Types I and IV 'phages have little or no reaction, although the organisms may or may not have a *Vi* antigen content.

From a series of symptomless carriers in one area there were isolated "rough" typhoid organisms, suggested by the biochemical findings, for they were auto-agglutinable in both normal and 0·2 per cent saline solution. Observation of the cultures showed them to be heavily contaminated with a naturally occurring anti/*O* 'phage. When the 'phage content was reduced in amount, the agglutinations were characteristic, and the organisms reacted with confluent lysis to I and IV 'phages and also were all lysed by specific Type II *G* 'phage. This series was presumed to be an example of excessively 'phage-contaminated Type *G S. typhi*, which had spread from one person to another in the roughened form.

This technique of growth in anti-phage serum was applied to a series of previously untypable strains, and most of them have now been assigned to known 'phage types. Most difficulty arises with the subgroup characterized by its pattern reaction, for although these strains can be altered to the second group (that is, lysis only with pooled I and IV 'phages), so far it has not been easy to classify them further.

These three subgroups would seem to be due to the same biological process in action. The groups are not clear cut and merge into one another. The individual variation of $V — VW — W$ seems to run parallel to the colonial population change of smooth to rough in that the roughness is due to the same process acting on smooth organisms.

It would seem that bacteria contaminated with bacteriophage show the phenomenon of partial and complete interference to specific 'phage action. The loss or lowering of bacterial resistance to concomitant 'phage is responsible for the change from $V—VW—W$ and even to *rho* forms. Outbreaks of typhoid fever have occurred, where the *S. typhi* isolated gave partial or complete interference to specific 'phages and rendered the organisms untypable, in that they could not be assigned to group 1—24. It is of interest to note that untypable forms occur towards the end of outbreaks caused by specific 'phage types. When these previously untypable strains are rendered typable by the above method, they are found to be of the same 'phage type as the outbreak. As with communities, so with individuals, it is not infrequent that in a clinical relapse the organism isolated is of the untypable group. Examples of these untypable *S. typhi* from relapses have been identified as being of the same 'phage type as the initial infection.

Bacteriophage is widely distributed in Nature. Among the Gram-negative bacilli, 'phages have been isolated here from *S. typhi*, paratyphi *A*, *B* and *C*, various other members of the *Salmonella* group, most strains of dysentery, *Proteus*, *Pyocyaneus* and Coliforms, and they are especially numerous on Paracolon organisms. It would seem as if most of these organisms have the weakness whereby they lose their resistance to 'phage and become contaminated. From this point of view, it is not happy symbiosis, for the contamination alters the organism.

Distribution of Shell Porphyrins in Mollusca

RED fluorescence due to porphyrins in molluscan shells has been known for some years (Furreg and Quemer, 1929; Fischer, 1930, 1934, 1937; Waldenström, 1937; Tixier, 1945); but its exact distribution has not been described. In an investigation of the phylogenetic relationships of shell pigments, I have examined some three thousand species from many gastropod and pelecypod genera by ultra-violet fluoroscopy. Detailed findings in this investigation, together with data on the chemistry of shell porphyrins and other acid-soluble pigments, will appear in due course in the *Biochemical Journal*.

The distribution of porphyrins follows the known anatomical affinities of molluscs very closely. They occur widely in the Archæogastropoda, but disappear among the Turbinidæ, in which Krukenberg (1883) and Tixier (1947) have demonstrated a predominance of linear tetrapyrroles, and are absent from the Mesogastropoda as far as the Lamellariacea. A focus of porphyrin deposition covers this section and overlaps into the Cypræacea. The characteristic fluorescence recurs in the tectibranch opisthobranchs and in *Umbraculum*. Isolated species of *Marginella*, and one species of *Torinia*, also deposit porphyrins. Among the pelecypods, I found them in the Anomiidæ, Pinnidæ and Pteriidæ, and in *Venus* (*Clausinella*) *fasciata*, *Gafrarium divaricatum* and *Sunetta solanderi*.

They were absent from other pelecypods examined. No porphyrins were detected in the shell of any land form, or of any freshwater pulmonate.

The main genera in which shell porphyrins have been shown to occur are listed below, the sign * indicating that the property is widespread in the group.

Clypidina
*Fissurella
Lucapina
Acmæa
*Trochus
*Clanculus
*Ethalia
*Isanda
*Monilia
Thalotia
Elenchus
*Umbonium
Gibbula
Livona
Monodonta
*Angaria
Leptothyra
Lithopoma
Tricolia
Theodoxus
Neritodryas
Neritina
Torinia
*Trivia
*Erato
*Velutina
Cypræa
Marginella
Hydatina
*Bulla
Acteon
Haminea
*Aplustrum
*Umbraculum
Enigmoma
Anomia
*Pteria
*Pinctada
*Malleus
Isognomon
Pinna
Venus

They occur also in several Loricates, and in two Scaphopods.

Distribution in the outlying groups is well localized: in *Cypræa* it is confined to the section *Luria* (*cinerea, isabella, pulchra*), *Erronea subviridis* and *Cypræa mappa*. In *Marginella*, it centres round *M. ornata*. Individual variation is very marked. The pattern of distribution in an individual species may or may not coincide with the visible pigment; in some forms it is generalized, in others confined to a single band or patch. In *Gibbula cineraria*, only the topmost whorl and protoconch usually fluoresce.

The porphyrin content of most forms is chromatographically separable from the main colouring matter. Details of the pigments detected, which are numerous, and of the identity of the porphyrins, will be given in forthcoming papers.

Marked porphyrin fluorescence was detected not only in *Gibbula cineraria* from the Clyde Beds (post-Pleistocene), but also in *Pteria media* from the London Clay and several species from the Calcaire Grossier (Paris Basin, Upper Eocene), namely, *Fissurella squamosa* Desh., *Angaria calcar* Lk., *A. lima* Lk., *Tectus crenularis* Lk.

The following is a list of British recent Mollusca found to deposit shell porphyrin:

Patelloida virginea Mull.
Gibbula magus da C.
Gibbula cineraria L.
Cantharidus striatus da C.
Monodonta lineata da C.
Tricolia pullus L.
Theodoxus fluviatilis L.
Velutina velutina Mull.
Erato voluta Mont.
Trivia monacha da C.
Trivia arctica Mont.
Acteon tornatilis L.
Venus fasciata da C.

Oscillographic Analysis of the Gravity and Vibration Responses from the Labyrinth of the Thornback Ray (*Raja clavata*)

IN a recent communication[1], one of us (O. L.) reviewed the results so far obtained, by the oscillographic method, in the study of the non-acoustic function of the vertebrate ear. In that review a preliminary account was given of the reaction to gravitational stimuli and linear accelerations of the otolith organ in the recessus utriculi of the elasmobranch labyrinth. It was shown that the otolith organ of the utriculus is sensitive to positional changes about any horizontal axis, and to linear acceleration during straight-line translations. The fact that the organ is not restricted to respond to displacements in only one plane of space invited the conclusion that the utriculus may well be the only otolith organ concerned with the maintenance of equilibrium, leaving the otolith organs of the pars inferior of the labyrinth (sacculus and lagena) free for the reception of vibrational stimuli. This function has, in fact, been conclusively demonstrated to be localized in the pars inferior of the labyrinth of bony fish[2,3].

During the past summer we have been able to extend our electrophysiological experiments on the labyrinth of the ray to the pars inferior, and we have succeeded in obtaining, by direct recording from the nerve branches supplying all its sensory epithelia, single-fibre responses of accurately localized origin. The results, the quantitative aspects of which are at present being analysed and prepared for publication elsewhere, can be qualitatively summarized as follows.

In the elasmobranch labyrinth the utriculus is not the only gravity receptor. Equally good but qualitatively different gravity responses can be recorded from the otolith organs of the sacculus and of the lagena. In the lagena the whole macula acts as a gravity receptor, whereas in the sacculus gravity responses are confined to the posterior part of the macula immediately adjoining the lagena. The lateral part of the sacculus macula, which is innervated by a number of separate branches of the ramus inferior of the eighth nerve, shows clear and characteristic nerve-impulse responses to low-frequency vibrations of the substrate. These spike responses are accompanied, but in our opinion not caused, by the well-known Wever – Bray or 'cochlea' effects, which can always be picked up from the membranous wall of the exposed labyrinth during vibrational stimulation[3-7].

Apart from the lateral part of the sacculus macula, the sacculus was found to contain yet another highly sensitive vibration receptor. This is the macula neglecta, which is lodged in the medio-dorsal aspect of the sacculus and is innervated by a separate long nerve branch, containing relatively thick and therefore rapidly conducting fibres. The sensorium of the macula neglecta is small and not covered by a lime-encrusted otolith membrane. It lies opposite a large membrane-covered window in the dorsal wall of the cranium, which was first described by Scarpa[8] as fenestra ovalis, a term which assumes a new significance in the light of our experiments. This is, so far as we are aware, the first information about the hitherto completely unknown function of the macula neglecta of the vertebrate labyrinth.

The vibration response of the elasmobranch labyrinth is, however, not confined to the pars inferior. The utriculus macula is only partly covered by its lime-encrusted otolith membrane. An uncovered portion of it, the lacinia, extends upwards to the roof of the recessus utriculi. We were able to isolate the nerve twigs supplying the lacinia and obtain single-fibre spike responses to vibrational stimuli, which did not materially differ in range and sensitivity from the saccular responses. In contrast to the immediately adjacent parts of the otolith-bearing utriculus macula, the lacinia does not respond to positional changes.

The experiments described above thus bring to a conclusion the point by point oscillographic analysis of the function of all known sensoria of the elasmobranch labyrinth on the basis of accurately localized single-fibre responses.

This summer's work was again carried out at the Laboratory of the Marine Biological Association at Plymouth with the aid of a Royal Society grant from the Parliamentary Grant-in-aid of Scientific Investigations, while one of us (O. L.) was privileged to hold the Physiological Society's Table at that Laboratory. Our special thanks are due to the director and staff of the Laboratory for their most generous support in providing the considerable amounts of living material and technical research facilities without which the work would have been impossible.

Delayed Neutrons

IN his paper "Mechanism of Nuclear Fission", Bohr[1] has explained the emission of delayed neutrons from certain members of the fission chains as due to the product being in a sufficiently highly excited state after the emission of β-particles. Of the other possibilities, production of delayed neutrons by (γ,*n*) reaction by the γ-rays after a β-disintegration, following Bohr, can be excluded simply because of the absence of sufficiently energetic γ-rays in fission chains reported in the Plutonium Project Report[2].

There is, however, another type of reaction, namely, electro-disintegration or (*e*,*n*) reaction, the possibility of which for the emission of delayed neutrons cannot be ruled out. Recent experiments of such reactions on heavy elements by Skaggs *et al.*[3] have shown that these reactions have cross-sections less than those for photo-disintegration only by a few hundred times, and the reports[4,5] of photo- and electro-disintegration of Be^9 show definitely that their threshold energies are exactly equal. These facts lead to the conclusion that photo- and electro-disintegrations are sister reactions differing in their cross-sections only. As a matter of fact, we may infer that delayed neutrons would be ejected, by a process similar to electro-disintegration, spontaneously in the nucleus itself, by those particles of unusually high energy emitted by certain members of the fission chains, for example, Kr^{87} and Xe^{137}. As a result, though the neutron emission is instantaneous, they will be emitted throughout the half-life of β-emission analogous to the case of the γ-emission which, though instantaneous, yet follows the preceding β-life. This has been found actually to be the case for Kr^{87} and Xe^{137}, where neutrons follow the β-life. Our inference is that the high-energy electrons are responsible for ejection of neutrons from Kr^{87} and Xe^{137} by electro-disintegration.

Recently, workers[6] in the Berkeley Laboratory have detected a delayed neutron emitter in the low mass-number region by bombardment of the oxygen nucleus with 195 MeV. deuterons. According to them, N^{17} changes to O^{17} by emission of β-rays, and this O^{17} in its turn ejects delayed neutrons. But from the point of view of electro-disintegration, we may infer that it is N^{16} which emits β-rays of $\sim 6{\cdot}2$ MeV. and goes over to O^{16}. The remaining nuclei of N^{16} are undergoing electro-disintegration simultaneously by these high-energy β-particles, and become N^{15} by emission of delayed neutrons, so that N^{16} and not O^{17} is the delayed neutron emitter. This assignment of N^{16} fits in exactly with the scheme of disintegration found in the case of Kr^{87} and Xe^{137}, whereby the nuclei of the same element emit β-radiation and neutrons simultaneously.

Reduction of Dead Times in Geiger – Müller Counters

THE significance of the positive ion sheath, formed in the immediate vicinity of the wire in a Geiger – Müller counter during a discharge, has been discussed by the Montgomeries[1] and by Stever[2]. According to them, the positive ion sheath is directly responsible for the dead time occurring in the counter after each discharge; the dead time is identified with the time necessary for the sheath to move sufficiently far from the wire for the field to be restored to a value at which the next event can be detected. Following this, Simpson[3] and Hodson[4] investigated the possibility of reducing the dead time by bringing the ion sheath back to the central wire and collecting it there. For this purpose they employed circuits by means of which the wire potential could be switched about 100 volts negative with respect to the cathode for a few microseconds after each discharge. Dead times as low as 20–30 microsec. were obtained in this way.

A consideration of this problem suggested that the major part of the reduction in dead time achieved was not due to positive ion collection but to the localization of the ion sheath, which is thus prevented from spreading along the whole of the wire, leaving the remainder of the counter sensitive to further ionizing events. This possibility is consistent with the known spread velocity of the ion sheath[5–7] and with the estimated operating speed of the circuit.

In order to confirm this suggestion, and to show that it is not necessary to reverse the wire potential and resort to ion collection to obtain shorter dead times, a circuit has been used to reduce the wire potential to within 20–30 volts of that of the cathode for about 1 microsec. after each count. Pulses from a counter operated in this way have been observed on a triggered cathode ray oscillograph, and dead times of 3–4 microsec. have been obtained, the limit being imposed by the recovery time of the electronic circuit. The dead times in this case refer to the counter as a whole; individual parts of the counter involved in any one count may be insensitive for much longer periods.

Further confirmation has been obtained in an experiment using a brass-walled counter, 38 cm. long and 2 cm. in diameter, filled with 10 cm. pressure of argon and 1 cm. of alcohol. This counter was operated both with and without the switching circuit. Photo-multipliers (RCA 931 *A*), mounted opposite mica windows in the counter wall at each end of the tube, registered the counts occurring in these regions of the counter. A suitable counting-rate was obtained when beta-rays from P^{32} were passed into the counter, at right angles to the wire, through an aluminium window at one end.

	End near source (counts per min.)	End remote from source (counts per min.)
Normal operation	3614	3736
Counter operated with switching circuit	3526	42

The results quoted in the table are average values and have been corrected for the background. The first column gives the counting-rate registered by the photo-multiplier at the end of the counter near the source, while the second column shows the counting-rate at the other end. It is seen that when the circuit was operating, 99 per cent of the discharges did not reach the far end of the counter and were localized near the source end of the counter.

A similar experiment, performed with a collimated beam of gamma-rays and using a divided cathode counter, kindly lent by Dr. Craggs, has shown the same effect.

Circuits in which the wire voltage is reduced instead of being reversed have the great advantage that spurious counts are less likely to occur. This is so because, in the case of positive ion collection on the wire, there is a possibility of producing secondary electrons from the wire by the ionic bombardment[8] and subsequent formation of negative ions. An increase in the rate of spurious counts has indeed been observed when reversing circuits have been used under the same conditions.

Finally, it is suggested that the pulses from a photo-multiplier, used to detect the light produced during the formation of the ion sheath, might find applications where fast rise times are required. This possibility is being investigated.

Crystal Structure of *d*-Tartaric Acid

WE have been making a study of the crystal structure of *d*-tartaric acid by X-ray analysis. This is a classical substance which presents some little difficulty in complete analysis owing to its low symmetry and to the absence of a heavy or replaceable atom.

The unit cell dimensions obtained by us were in agreement with those reported by Astbury[1] and by Reis and Schneider[2], but the structure suggested by Astbury did not agree with our X-ray intensity data. We took sets of Weissenberg photographs about the three principal crystallographic axes, and calculated sections of the Patterson function at various *y*-levels. These sections enabled an approximate structure to be derived quite quickly. This structure gave fair intensity agreement of the (*hk*0), (*h*0*l*) and (0*kl*) planes, and permitted the evaluation of Fourier projections down the three axes. These projections are now being used to obtain more accurate values of the parameters.

A complete description of the structure is as follows: class, monoclinic sphenoidal; space group $P2_1$; cell dimensions, $a = 7{\cdot}73$, $b = 6{\cdot}05$, $c = 6{\cdot}18$ A., $\beta = 100^\circ\ 17'$, containing two molecules $C_4H_6O_6$; parameters in hundredths of cell edges (apart from a possible inversion through the origin):

	x	*y*	*z*		*x*	*y*	*z*
O_1	35	0	51				
O_4	43	0	99	C_2	30	99	28
O_5	61	99	31	C_3	45	1	19
O_7	31	41	26	C_6	20	21	17
O_9	94	8	17	C_8	3	22	26
O_{10}	98	40	34				

The molecule has essentially the same configuration as in Rochelle salt[3], and neighbouring molecules are held together by a system of hydrogen bonds. The structure is still in need of refinement, and it is hoped to publish later more accurate values of the parameters, together with fuller details of the work summarized above.

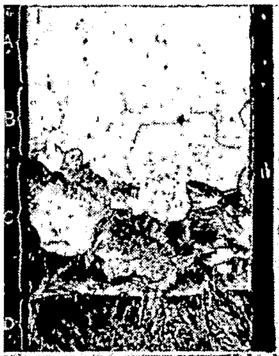
Intergranular Corrosion of Pure Aluminium in Relation to the Behaviour of Grain-Boundaries during Melting*

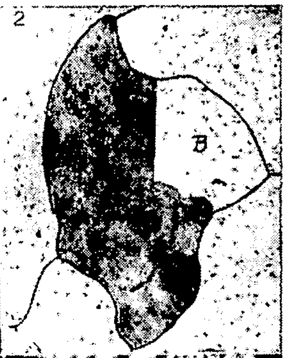
IN two previous papers[1,2] we showed in the case of pure aluminium recrystallized by the 'critical deformation' method that the rate of etching of the grain boundaries by hydrochloric acid was more influenced by the relative orientations of adjoining crystals than by impurities in the metal itself. Thus the grain boundaries in two aluminium specimens of 99·99 and 99·998 per cent purity were corroded at the same rate in the case of crystals oriented at random, whereas the boundaries separating crystals of nearly identical relative orientations, or straight twin boundaries[2], were not corroded at all, regardless of the duration of etching and the concentration of the reagent. We have already reported a similar effect[3] when studying the micrographic etching of boundary lines in high-purity aluminium.

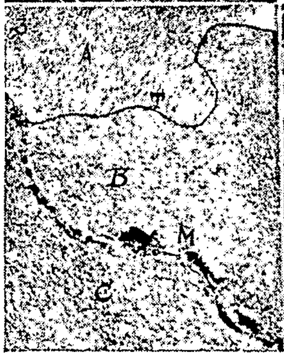
In order to compare the crystal boundaries obtained by recrystallization in the solid state with those obtained by solidification, we have been led to a careful study of the melting process itself. Chalmers[4] showed that the grain boundaries of high-purity tin had a melting temperature lower than that usually accepted for tin in the mass. We have now observed a similar effect in the case of high-purity aluminium by employing a simple device which was used by one of us[5] in the study of supercooled aluminium.

* Translation by Dr. N. Stuart.

A rectangular piece of metal, 1 mm. thick and 10 mm. × 130 mm. surface, was heated on a perfectly horizontal kaolin block inside a furnace permitting of a temperature gradient of 10° between the ends of the sample, so that one end may be molten while the other remains solid. If the metal is previously polished electrolytically, a zone may easily be observed (Fig. 1) as hollow lines where only grain boundaries are molten. The twin boundaries remain unaltered, however, thus giving evidence of a melting temperature nearly or quite equal to that of the crystals themselves (Fig. 2), and, as in the case of intergranular corrosion by hydrochloric acid, these also possess peculiar properties.







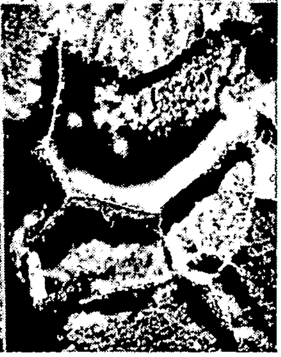


Fig. 1. Transition of melted to solid metal: *A*, entirely solid metal; *B*, boundaries only melted; *C*, partially melted crystals; *D*, entirely melted. (× 1)

Fig. 2. Unmelted twin boundary among melted ordinary boundaries. (× 5)

Fig. 3. Difference of intergranular corrosion between an unmelted boundary *T* and a melted boundary *M*. (× 5)

Fig. 4. Inverted corrosion by 30 per cent hydrochloric acid on pure aluminium heated for 15 hr. near the melting point. (× 5)

It might be thought that this characteristic behaviour of the boundaries during melting is related to their more or less disordered 'transition' structure, and that as a consequence of this their etching by hydrochloric acid would be different according to the relative orientations of adjacent crystals. Actually, as is shown in Fig. 3, the width of the intergranular groove due to etching in 30 per cent hydrochloric acid is very small and constant in the case of a sinuous twin boundary which had not been melted, whereas it is very large and irregular in the case of the molten boundary separating crystals of random orientation.

In conclusion, when the metal was heated for a long time (15 hr.) near the melting point, we observed, in certain cases, an inversion of the corrosion; for example, hydrochloric acid only dissolved the bulk of the crystals, leaving their boundaries uncorroded as a very thin surviving partition (Fig. 4). We intend to investigate how this inverted corrosion occurs.

A New Carbide in Chromium Steels

In the course of X-ray investigations on the carbides formed in chromium and tungsten steels, a phase was encountered of a crystal structure identical with that of austenite, which at first it was thought to be. In fact, it proved to be a true carbide of iron and chromium. Its carbon content of 9·4 weight per cent carbon is similar to that in Cr_7C_3 (9·1 per cent C), compared with the maximum carbon solubility in austenite of only 1·7 per cent (at the eutectic in the iron–carbon system, chromium only decreasing this value). The carbides known in plain chromium steels since Westgren's[1] early researches are $(Cr,Fe)_{23}C_6$, $(Fe,Cr)_3C$ and $(Cr,Fe)_7C_3$, all of which, as well as the present one, I found it possible to produce in the same steel by different heat-treatments. The carbide is believed to be of interest for its own sake, but also for more fundamental reasons given below.

The structure, as in austenite, is face-centred cubic, with interstitial carbon to approach the NaCl type of lattice possessed, for example, by titanium, vanadium and niobium carbides. The cube edge is $a_0 = 3\cdot6111$ kX. ± 0·0002, but variations in Cr : Fe ratio, and in carbon content, and therefore spacing, are liable to occur, and the lattice is probably a defect one. The carbide is non-magnetic.

The compound is stable only at high temperatures, but by quenching the steel it can readily be retained at room temperature in a metastable state. On annealing at 1,000° C. or at lower temperatures, true trigonal $(Cr,Fe)_7C_3$ is formed. The carbide was obtained by electrolytic extraction from a 6 per cent chromium, 1 per cent carbon steel, quenched from 1,250° C., the resulting phase-constitution being:

Extract	Bulk steel (before extraction)	
'Austenite'—large amount.	Martensite—large amount	(*A*)
$(Cr,Fe)_7C_3$—small amount.	'Austenite'—small amount.	

After a heat-treatment aimed at low-temperature equilibrium (anneal at 800° C., 3 hr., then 590° C., 3 hr.), the same steel showed, in contrast:

Extract	Bulk steel	
$(Cr,Fe)_7C_3$—almost pure	Ferrite—large amount.	(*B*)
Cementite—trace.	$(Cr,Fe)_7C_3$—medium amount	

The carbon analysis of extract *A* gave 9·4 per cent carbon, of *B*, 8·7 per cent carbon, that is, both closely surround the Cr_7C_3 value of 9·1 per cent carbon. (The slight deficiency in *B*, if significant, falls into line with the presence of cementite, while the excess in *A* suggests a stoichiometric formula for the cubic carbide, yet richer in carbon than *Me*$_7$C$_3$, such as *Me*$_2$C.) To differentiate the carbide from austenite it will here be referred to as 'ψ'.

From the point of view of structure chemistry, the present carbide may be shown to fall naturally into place. Petch[2] has shown that in austenite the carbon atoms occupy the octahedral positions; but, even for maximum saturation, only one among twelve of these sites is filled. On the other hand, within the group of carbides of NaCl type of structure, carbon atoms begin to be omitted from the ideal *Me*C lattice in a manner complementary to the austenite solid solutions, as becomes apparent when arranged according to the periodic table:

$$\begin{tikzcd}
\text{Group:} & \text{IV} & \text{V} & \text{VI} & \text{VII} & \text{VIII} \\
\text{Cubic carbides:} & \text{TiC} \arrow[r] & V_4C_3 \arrow[r] & \begin{array}{c}\psi\text{-phase}\\ (Cr,Fe)_7C_3 \text{ approx.}\end{array} \arrow[rr] \arrow[dr] & & \begin{array}{c}\text{austenite}\\ (Fe,Mn,Co,Ni)_nC\end{array} \\
 & \text{ZrC} \arrow[r] & Nb_4C_3 & & {[(Cr,Mn,Fe)_{23}C_6]} \arrow[ur] & \\
\text{Metal/carbon atom ratio:} & 1 & 1{\cdot}3 & 2{\cdot}3 & 3{\cdot}8 & \geqslant 12
\end{tikzcd}$$

In this series, chromium and manganese occupy transitional positions; of their carbides, one simulates the cubic, one the hexagonal, and one the orthorhombic symmetry of those of the surrounding elements (V_4C_3, Mo_2C and Fe_3C respectively). But $(Cr,Mn,Fe)_{23}C_6$, though belonging to the cubic class, does not actually adopt the NaCl structure, having a complex unit cell with 116 atoms. The ψ-phase thus bridges a gap between austenite and the rock-salt type of carbides, being isomorphous to both and consistently falling into the above sequence of metal/carbon ratios. In this light, austenite may, incidentally, be itself regarded as a 'carbide', being the ultimate member of the cubic group.

The substitution in ψ of chromium by manganese, to give an analogue to ψ in plain manganese steels, is highly probable, though its existence has not, to my knowledge, been reported and may well in the past have been obscured by the predominant austenite.

The following implications of the ψ-carbide are suggested.

(1) Its existence imposes caution in interpreting an apparent austenite as such, when occurring in a ferrite or martensite matrix. Spacing measurements or the microscope will not necessarily decide between austenite and ψ. In high-speed steels, for example, the 'persistent' portion of retained austenite which only repeated tempering can destroy is quite liable to involve carbon-enriched ψ, or a solid solution of its type.

(2) The carbide can be produced in chromium-bearing tool or magnet steels, where, in view of its structure and composition, it would tend to induce physical properties compromising between a hard carbide and the more ductile austenite.

(3) Being stable only at high temperatures (though metastable at lower ones) and tending to transform into either trigonal $(Cr,Fe)_7C_3$, $(Cr,Fe)_{23}C_6$ or cementite, or assemblies thereof, the carbide holds promise of showing precipitation hardening effects, that is, by one carbide nucleating within another.

(4) Since the lattice dimensions are favourable to the formation of high-temperature solid solutions with austenite in chromium–nickel heat-resisting and stainless steels (but only for certain composition ranges), its tendency to segregate from the matrix and at the same time itself to decompose is likely to influence creep-resistance and high-temperature strength. X-ray analysis conducted in these laboratories on heat-resisting steels actually reveals sequences of ostensible 'austenites' of varying lattice parameter, some of which probably represent ψ-phases intermediate in composition to the austenite base and the co-existing close-packed cubic TiC type carbides.

(5) Prepared synthetically, ψ is a carbide of possible interest in sintered hard-metal materials, particularly being isomorphous with titanium carbide as well as with metallic cobalt and, on structural grounds, probably also intersoluble with tungsten carbide.

An account of the work on carbides in steels, of which this forms part, will be published elsewhere. I wish to thank Mr. D. A. Oliver, director of research, B.S.A. Group of Companies, for his interest and encouragement, and Mr. E. Harpham for the carbide extractions.

Photochemical Action of Ethylorthoformate

Ciamician and Silber[1] showed that when an ethyl alcohol solution of benzophenone is exposed to sunlight, the alcohol is oxidized to aldehyde and the ketone reduced to benzpinacol; in the place of ethyl alcohol, *iso*propyl alcohol has frequently been used[2].

$$2\,Ph_2C:O + CHMe_2OH \xrightarrow{\text{sunlight}} Ph_2COH.COHPh_2 + Me_2CO.$$

A large number of benzophenone derivatives react in the presence of alcohols as above[3].

In a number of cases, pinacols have frequently been obtained from diaryl ketones, as by-products, when the ketones were treated with aromatic hydrocarbons, for example, toluene[4], or ether, *iso*-amylether, acetal and dimethylether of glycerol[5], or with esters, such as ethyl acetate, ethyl malonate[5], or acids, for example, phenylacetic acid[6]. The action of aliphatic alcohols on quinones, for example, *p*-benzoquinone in sunlight, yields hydroquinone[7]. Benzil, in absolute ethyl alcohol, forms benzilbenzoin[8].

Recently, I have found that on exposure to sunlight of benzophenone, *p,p'*-ditolylketone, *p,p'*-dimethoxybenzophenone and *p,p'*-dichlorobenzophenone with ethylorthoformate in sealed 'Pyrex'-glass tubes, the corresponding pinacols, namely, benzpinacol, 4 : 4′ : 4″ : 4‴-tetramethyl-, 4 : 4′ : 4″ : 4‴-tetramethoxy- and 4 : 4′ : 4″ : 4‴-tetrachlorobenzpinacol were obtained; deoxybenzoin gave a deoxybenzoin-pinacol, whereas benzil yielded benzilbenzoin. On the other hand, the action of ethylorthoformate on *p*-benzoquinone, toluquinone, chloranil and phenanthraquinone, yielded hydroquinone, toluhydroquinone, tetrachlorohydroquinone and 9 : 10-dihydroxyphenanthrene respectively. Identification of the photo-products was carried out by melting point and mixed melting point determination with authentic specimens. In all these experiments, the fate of ethylorthoformate has not yet been investigated. Control experiments in the dark, but otherwise under identical conditions, showed no reaction.

The application of ethylorthoformate as a photochemical reducing agent in sunlight is still under investigation.

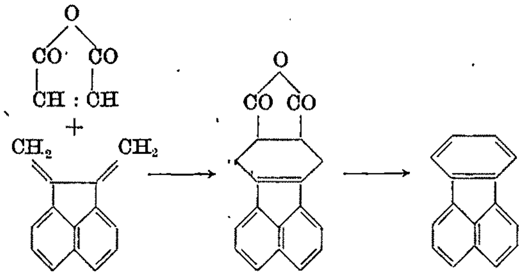
Fluoranthene Syntheses

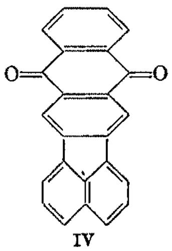
THE recent communication by Bergmann[1] on the formation of fluoranthene from acenaphthylene and butadiene prompts us to report briefly two somewhat similar syntheses of the hydrocarbon which have been developed in our laboratories.

trans-9 : 10-Dimethylacenaphthene-9 : 10-diol[2] when heated with acetic anhydride and maleic anhydride readily gives 10 : 11 : 12 : 13-tetrahydrofluoranthene-11 : 12-dicarboxylic acid anhydride (II), presumably by formation of the intermediate 9 : 10-dimethyleneacenaphthene (I)[3]. Dehydrogenation and decarboxylation of the product yield fluoranthene (III).

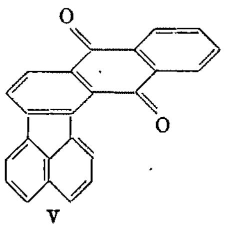


I II III

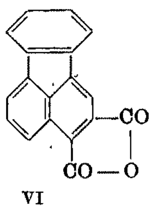
It is obvious that, by the use of substituted acenaphthenes or acenaphthenediols and replacement of the maleic anhydride by other ethylenic components, substituted fluoranthenes of known structure can be obtained. For example, substitution of maleic anhydride by α-naphthoquinone in the above reaction gives a quinone, melting point higher than 300°, which must have structure IV. The compound prepared by another method and regarded as having this structure[4] must be the isomeric quinone with formula V.



IV



V



VI

9-Methylfluorenol is known to undergo dehydration to the unstable 9-methylenefluorene[5]. By heating the carbinol with acetic anhydride and maleic anhydride, the intermediate methylene compound gives fluoranthene-3 : 4-dicarboxylic acid anhydride (VI), one of the nuclear double bonds being sufficiently reactive to participate in the Diels – Alder reaction. Decarboxylation gives fluoranthene (III). The reaction does not take place so readily as in the first method, but the structures of the products are unambiguously established.

Details of these and related experiments will be published elsewhere.

Sulphur-containing Steroid Derivatives

PREVIOUS communications[1,2] have recorded the synthesis of antibacterial compounds derived from bile acids and sterols which contained basic groups, such as the amino-, amidino- and guanido-groups. In general, these derivatives were bacteriostatic for Gram-positive bacteria, but had little activity against Gram-negative organisms. Whereas surface tension measurements seemed to reveal a relationship between the bacteriostatic and surface activities of the bile acids and their anionic derivatives[3], no such relationship was apparent in the properties of a series of the basic steroid compounds[4]. In an extension of these studies, we have synthesized and investigated several water-soluble, sulphur-containing, steroid derivatives.

A series of mercaptals has been obtained by the condensation of thioglycollic acid with various keto-derivatives of steroids, a reaction which occurs without a catalyst and appears to be specific for a keto group at position 3. For example, 3 : 7 : 12-triketocholanic acid yielded 3 : 3-di-(carboxymethylmercapto)-7 : 12-diketocholanic acid, m.p. 203°, $[\alpha]_D^{24°} + 55\cdot0°$; (trimethyl ester : m.p. 78°, $[\alpha]_D^{17\cdot5°} + 51\cdot3°$); 3-keto-7 : 12-dihydroxycholanic acid gave 3 : 3-di-(carboxymethylmercapto) - 7 : 12-dihydroxycholanic acid, m.p. 141°, $[\alpha]_D^{20°} + 35\cdot7°$; and Δ^4-cholesten-3-one afforded 3 : 3-di-(carboxymethylmercapto)-Δ^4-cholestene, m.p. 122–124°, $[\alpha]_D^{18°} + 108°$. 3 : 3-Dithiophenyl-7 : 12-diketocholanic acid was derived from the condensation of thiophenol with 3 : 7 : 12-triketocholanic acid by a modification of the method of Mylius[5]. In a similar manner, 3 : 3-di(N-acetyl-*p*-aminothiophenyl)-7 : 12-diketocholanic acid : m.p. 165°, $[\alpha]_D^{18°} + 13\cdot0°$, was obtained by the condensation of N-acetyl-*p*-aminothiophenol with 3 : 7 : 12-triketocholanic acid. The monobasic, sulphur-containing acid, 3-carboxymethylmercapto-Δ^5-cholestene, m.p. 145°, $[\alpha]_D^{21°} - 34\cdot2°$, was obtained by the reaction of thiocholesterol with monochloroacetic acid.

Treatment of the sodio-derivative of thiocholesterol with methyl iodide afforded the methyl thioether, m.p. 141°, $[\alpha]_D^{18°} - 24\cdot6°$, which gave, upon further treatment with methyl iodide, Δ^5-cholestene-3-

dimethyl sulphonium iodide, m.p. 165°, $[\alpha]_D^{19°}$ $-27 \cdot 7°$. This basic derivative was water-soluble, and its antibacterial activity against *Staph. aureus* was among the highest yet reported for a steroid derivative. A more detailed account of these and related studies will be published elsewhere[6].

An indication of the bacteriostatic activity shown by the new compounds against *Staph. aureus* is shown by the data below. The figures in the second column refer to the limiting dilution bacteriostatic for *Staph. aureus*, tested for 24 hours at 37° C.

3 : 3-Di(carboxymethylmercapto) 7 : 12-dihydroxycholanic acid	1 : 4,000
3 : 3-Carboxymethylmercapto-Δ^5-cholestene	1 : 2,500
3 : 3-Di(N-acetyl-*p*-aminothiophenyl)-7 : 12-diketocholanic acid	1 : 10,000
Δ^5-Cholestene-3-dimethyl sulphonium iodide	1 : 20,000

Construction of Troughs for Use in Chromatography Tanks

PREVIOUS workers[1-3] have described methods for the construction of troughs for use in chromatography. In this laboratory, a simple method of making troughs has been evolved which does not require any special apparatus or skill. The finished trough, owing to the uneven edge of the glass, does not require a glass rod or strip to hold the papers in place.

The materials required are 'Pyrex' or other similar glass tubing of the required bore (1–1½ in.), a gas-air blow-pipe and a 6-in. file with pointed tang. Any type of file or similar instrument will do, providing that the tang is about 2 in. long and the blade big enough to hold in the hand. The selected length of tubing is held securely on an asbestos-topped bench by an assistant. The operator warms about 4–6 in. of the end with a brush flame, and then, using a small intense flame, heats an area about ½ in. square until soft, at which stage the file tang is pushed in and the glass pulled out towards the operator. The flame is brought backwards about ½ in. and the above repeated until a slit 4–5 in. long has been produced: the ragged edges are now heated and smoothed back with the file, and the whole annealed with a brush flame. A further 4–5 in. is now done and the above repeated until a slot of the required length has been obtained. The ends of the tube are left open until the slot is finished, as this allows the flame to pass down and anneal the glass.

The trough is closed at each end by drawing out the tubing, and is adjusted in length by pressing the still hot ends on to an asbestos sheet. If a trough should fracture during manufacture or be accidentally broken, the pieces may be sealed at the ends and used in single-phase tanks. In this laboratory, two people, both unfamiliar with glass-blowin technique, can produce a 36-in. trough in half an hour

Origin of Fluctuating Galactic Noise

SINCE the discovery of discrete sources of radio radiation in the Milky Way, special attention ha been given to the rapid fluctuations shown by som of these. It seemed possible that these could be o the same kind as the 'bursts', occurring in the sola radiation of radio-frequency.

Ryle and Smith, studying the source in Cassiopeia at 80 Mc./s., made the very interesting observation that the variable component is probably not circularly polarized, and they therefore conclude that its origin must be different from that occurring near sunspots[1]

I should like to point out that at least three components of the solar radio-radiation should be distinguished: (1) the radiation of the quiet sun (2) the radiation of the disturbed sun, varying only slowly and depending on the number of spots; (3) the bursts. Component (2) shows circular polarization *but the bursts do not.* This seems to be well established by the observations of Payne-Scott, Yabsley and Bolton[2], at frequencies of 60 and 100 Mc./s.

Even if their result should not be general, it is clear that the random polarization of the fluctuation in Cassiopeia gives no evidence against an origin similar to that of the solar bursts. It therefore remains possible that these fluctuations are produced in individual stars. That they could be analogous to the disturbed solar radiation was already very improbable owing to the rapidity of the fluctuations and is entirely disproved now.

M. MINNAERT

Sterrewacht "Sonnenborgh",
Utrecht. Sept. 30.

[1] Ryle and Smith, *Nature*, **162**, 462 (1948).

[2] Payne-Scott, Yabsley and Bolton, *Nature*, **160**, 257 (1947).

PROF. MINNAERT has pointed out the distinction between the three components of solar radiation. We would like to make it clear that the primary objec of the experiment described in our previous communication[1] was to investigate the origin of the *steady* component of the radiation from the two intense galactic sources. The results which we obtained suggested that the steady component is produced by a mechanism similar to that of the 'thermal' radiation of the quiet sun.

The additional evidence, that the variable component appears to be unpolarized, has suggested to Prof. Minnaert that this component is analogous to solar 'outbursts'. We would agree that such a mechanism may be responsible, although we do not feel satisfied that there is sufficient evidence for the conclusion that solar 'outbursts' are unpolarized.

A TRAVELLING-WAVE LINEAR ACCELERATOR FOR 4-MeV. ELECTRONS

By D. W. FRY, R. B. R.-S.-HARVIE, L. B. MULLETT and W. WALKINSHAW
Atomic Energy Research Establishment, Harwell

THE basic principles of this type of accelerator and the details of a first model producing 0·5-MeV. electrons have already been described in *Nature*[1]. The accelerator here described follows the same general design, and as the phase velocity approaches the velocity of light the ratio of the inner radius of the corrugated guide to the air wavelength tends towards the same limit, namely, 0·2. The length has been increased to two metres with a radio-frequency power of 2·0 megawatts so as to accelerate electrons to the region of 4 MeV.

The corrugated wave-guide was designed to accept 45-keV. electrons from the gun and to bunch them about a stable phase position 45° in front of the point of maximum accelerating field, when the radio-frequency power is 2·0 MW. In the first 40 cm. of guide, the phase velocity was designed to be greater than the velocity of the stable electron, and such that the centre of the bunch moves from 45° to 35° as the phase oscillations die away. The accelerating field experienced by the stable electron increases from 17·5 kV./cm. to 20·5 kV./cm. (the peak field being 25 kV./cm. for 2·0 MW. of radio-frequency power). At 40 cm. the phase velocity was reduced to that of the stable electron and the phase angle maintained at 35° for the remainder of the two metres[2]. The measured phase error for the full two metres of corrugated wave-guide was found to be only 18° in 22 wave-lengths. The overall loss, including the improved form of feeds from rectangular to corrugated wave-guide, was 2·5 db.—hence the accelerator is still short of the efficient length[3,4].

The completed equipment, Figs. 1 and 2, resembles the first accelerator and has, in addition, a mismatch unit and phase shifter in the input rectangular wave-guide in order to pull the magnetron frequency, and an arrangement for automatically sweeping the magnetic field of the spectrometer in order to present a spectrum of output current versus energy directly on a cathode ray tube with a long afterglow.

The accelerator was first operated in February 1948. X-ray output was obtained immediately, at an energy between 3 and 5 MeV. (from lead absorption measurements). The energy was confirmed as being 4 MeV. with a simple form of spectrometer. The pulse of 4-MeV. electrons observed through the spectrometer was extremely narrow for low radio-frequency powers and was confined to the beginning of the 2-microsec. radio-frequency pulse. For larger radio-frequency powers the remainder of the pulse appeared at a somewhat lower energy. A small output was also obtained at about 1 MeV., the precise quantity and energy varying greatly with the general setting of the various controls and in particular the currents in the focusing coils. Under normal optimum conditions for 4 MeV., the 1-MeV. output was only a few per cent of the total.

Great difficulty was experienced in trying to measure directly the electron currents falling on the first collimating slit of the spectrometer, due to the large quantities of gas liberated by the radio-frequency power with the accompanying ionization effects. The beam was therefore allowed to pass into air through a copper window 0·005 in. in thickness (later replaced by the same thickness of aluminium). A lead target ⅛ in. thick was then used and a maximum X-ray yield of 3 roentgens per minute at a metre was obtained (this being limited by the maximum safe emission from the 0·2-mm. tungsten filament then in use). According to conversion figures then available, the mean current at 4 MeV. was computed as ¾ microamp. A direct measurement of the electron current falling on the lead target gave the considerably larger result of 3 microamp. The radio-frequency duty cycle was 1 part in 10,000 throughout (2-microsec. pulses—50 c./s.), giving a peak current of 7·5 milliamp. for a mean current of ¾ microamp. For a mean input power of 200 watts (2-MW. peak) the energy in the 4-MeV. beam was of the order of 3 watts; this was considered to constitute no appreciable loading during the measurements taken with the automatic spectrometer.

Since there was evidence that the beam was somewhat off the axis of the corrugated guide, the beam position and size were investigated with a fluorescent screen (willemite on mica) and a periscope system. The effect of the various focusing devices was readily

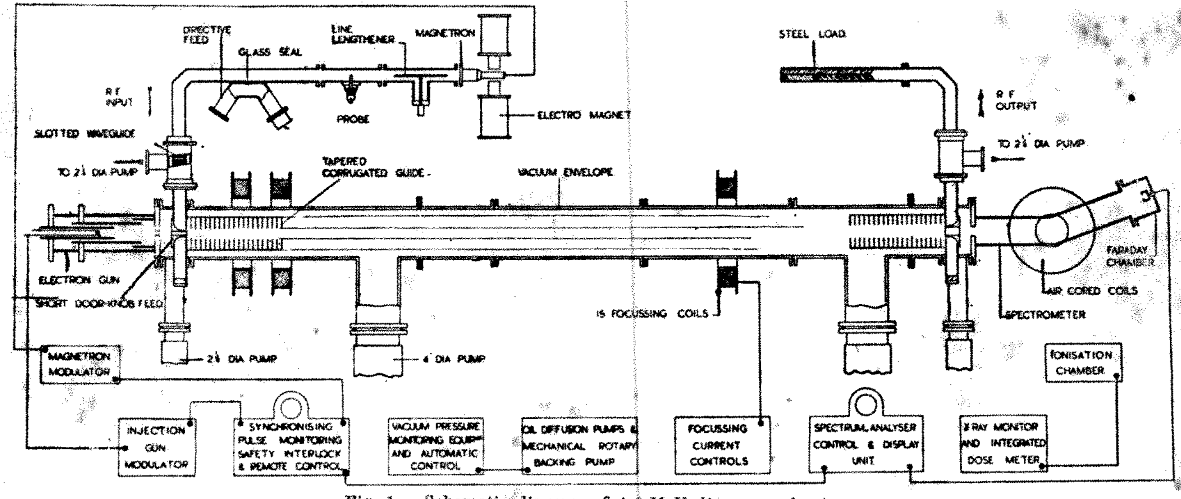

Fig. 1. Schematic diagram of 4·0-MeV. linear accelerator

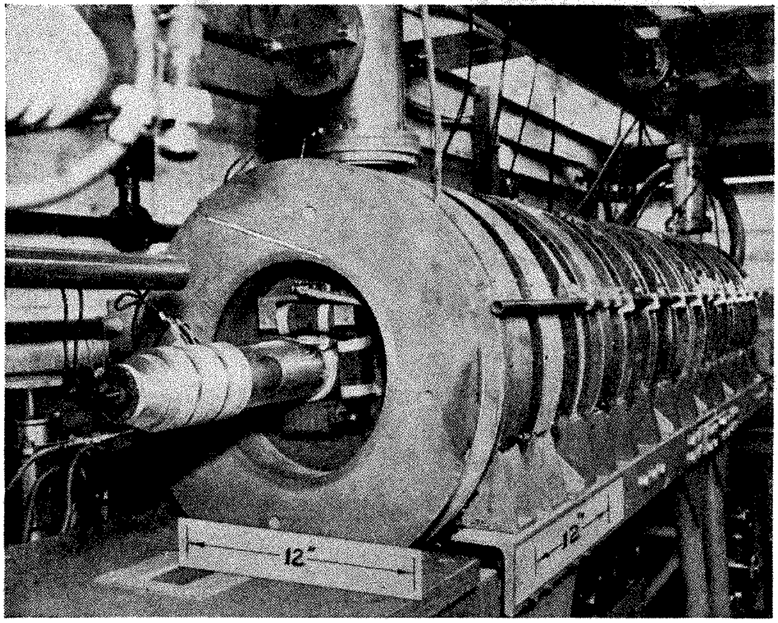

Fig. 2. Photograph of 4·0-MeV. linear accelerator, from gun end

observable. Under optimum conditions the spot size was certainly less than 1 cm. in diameter and probably of the order of 7 mm. No visible change occurred when a 2-mm. aluminium filter for 1-MeV. electrons was inserted. The spot was certainly off centre and could not be moved by varying the angle of injection of the 45-keV. electrons from the gun. Correction was eventually made with a small vertical magnetic field about 50 cm. down the accelerator.

A systematic investigation was then carried out using the automatic spectrometer for varying radio-frequency powers over a considerable range of radio-frequencies. A few energy spectra (Figs. 3 and 4) are given to illustrate the various phenomena observed. At the same time, X-ray measurements were taken as a rough indication of the number of accelerated electrons.

The design frequency was chosen to be 2997·8 Mc./s. ($\lambda = 10{\cdot}00$ cm.). Allowing for the measured phase discrepancy in the corrugated guide, the working frequency should be 2998·1 Mc./s. At the lower frequencies the stable phase position should move towards the peak of the wave as the electrons move along the accelerator, and eventually when the peak is reached there will be no stable position. This was observed to happen around 2995·5 Mc./s.—there being a very small output with an energy in the region of 3·6 MeV. for a frequency of 2995·6 Mc./s. At 2996·6 Mc./s. the spectrum was observable for a radio-frequency power equal to or greater than 1·9 MW. At 1·9 MW. (Fig. 3*a*) the spectrum had two distinct lobes which occurred at widely different energies. The output pulse, viewed on a time instead of an energy scale, consisted of a short spike (about ¼ microsec.) occurring at the front of the 2-microsec. pulse, and then the remainder of the pulse was not seriously broken up. This spike always provided the higher-energy component. As the radio-frequency power was increased, the total output current invariably rose and the spike or higher-energy component was drastically reduced. The presence of the spike is not understood, and it cannot be correlated with the frequency-time spectrum of the radio-frequency pulse, since it occurred for any radio-frequency spectrum provided that radio-frequency power and frequency were sufficiently low. In some cases it was interesting to note that the relative amplitudes of the higher- and lower-energy lobes could be altered considerably by varying the amount of external focusing. As the frequency was increased, the high-energy spike became almost unobservable except at the very lowest radio-frequency powers, and at 2998–2999 Mc./s. the width of the spectrum between half-amplitude points could be reduced to the order of 0·3 MeV. (Fig. 3*b*). It was suspected that some of this width was still due, however, to time modulation during the 2-microsec. pulse. At still higher frequencies the high-energy spike appeared again at the higher radio-frequency powers, together with a general broadening of the half-amplitude width.

The variation of energy of the spectrum peak with frequency for 2·0 MW. of radio-frequency power is shown in Fig. 4. It is evident that the accelerator functions in a satisfactory manner over a range of about 3 Mc./s. and is generally at its best at approximately 2998 Mc./s.

Having chosen a satisfactory working frequency (2998·8 Mc./s.) with 2·25 MW. of radio-frequency power, the effect of varying the gun voltage was investigated. There was a distinct threshold at 17·5 kV. and a steady rise in current output from this point upwards. The energy of the peak in the spectrum was about 4·5 MeV. at the threshold and

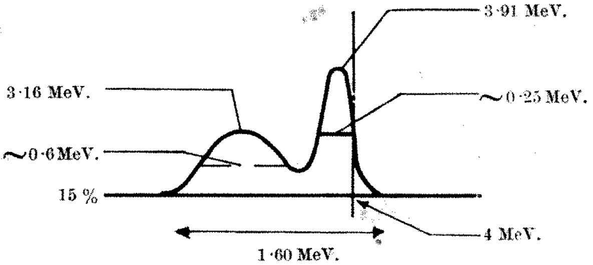

Fig. 3*a*. Radio-frequency 2996·6 Mc./s.; radio-frequency power, 1·9 MW.; ion chamber, 0·18 (full scale, 1·0)

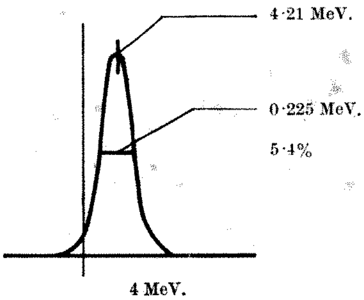

Fig. 3*b*. Radio-frequency, 2998·2 Mc./s.; radio-frequency power, 2·2 MW.; ion chamber, 0·36

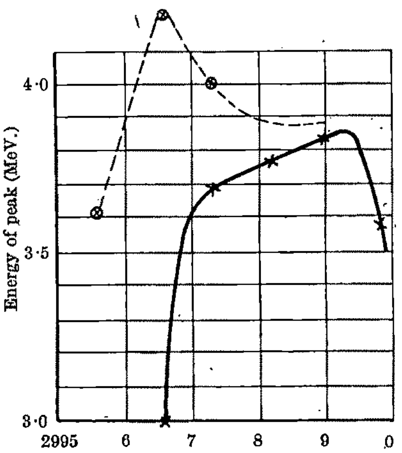

Fig. 4. Variation of the energy of spectrum peak with R.F. frequency. ⊕, high *E* spike

fell steadily to 3·85 MeV. at a gun voltage of 45 kV. The half-amplitude width of the spectrum increased rapidly, being 0·27 MeV. at 30 kV. and 0·42 MeV. at 40 kV. This behaviour was identical with that of the shorter 0·5-MeV. accelerator and can be explained in precisely the same manner. It was significant, however, that with the longer length of guide the energy variation was not so pronounced, although even in this case electrons at low injection voltages being picked up near the peak of the wave were still moving relatively slowly down to the true stable phase position.

Using the optimum conditions so far determined, and increasing the injected current by increasing the gun filament from 0·2 mm. tungsten to 0·3 and then 0·4 mm., the X-ray yield using a lead target ⅛ in. thick (and a 2-mm. lead filter for soft radiation) has been increased to 30 roentgens per minute at a metre at 50 c./s. recurrence-rate. By increasing the recurrence-rate the output has been scaled up to 66 r./min. at 100 c./s. and 132 r./min. at 200 c./s. The maximum permissible recurrence-rate, determined by the magnetron, is 500 c./s., giving a potential X-ray yield of 300 r./min. The output reached a maximum with the 0·4-mm. tungsten current at 12·6 amp., and no further increase could be obtained by going up to 14·0 amp., which should represent an enormous increase in emission. It was evident from the fact that at 30 r./min. a hole was very soon burnt through the lead target (and at 132 r./min., even with a strong blast of air on the bombarded side, burn-out was quite common) that the mean power in the beam was quite large and easily measurable by calorimetry. (It is interesting to note that the hole burned in the target was invariably about 7 mm. in diameter.) A continuous-flow water calorimeter was therefore constructed consisting of a lead target ⅛ in. thick with a circulating water film 7 mm. in thickness on the bombarded side. A small spiral heater of diameter comparable with that of the beam was mounted in the water near the target spot on the lead. Direct comparisons could then be made of beam power and power required in the heater to produce the same temperature difference between inflow and outflow as indicated by a thermocouple system. In this way it was established that the mean power in the beam at 50 c./s. under conditions which gave an X-ray yield of 30 r./min. was almost exactly 60 watts, giving a mean current of 15 microamp. and a peak current of 150 milliamp. if the energy was taken to be 4 MeV. Hence the highest current which has so far been obtained is 60 microamp. with a possible maximum of 150 microamp. at 500 c./s., the highest magnetron recurrence-rate. The efficiency in terms of radio-frequency power being fed into the accelerator is 30 per cent, and since the radio-frequency losses in the system are normally 2·5 db., it is understandable that no further increase in efficiency is readily obtainable. It has also been observed, using the spectrometer again, that the width of the spectrum is generally unaffected by increased beam current, but the energy of the peak falls by about 250 keV.

Acknowledgment is made to the assistance given to this project by our colleagues. This work was carried out by the Electronics Group of the Atomic Energy Research Establishment, at the Telecommunications Research Establishment, Malvern, and acknowledgment is made to Sir John Cockcroft for permission to publish these results.

SOUTH AFRICAN MUSEUMS

THE appointment of a commission to investigate and report upon the future policy of certain State-aided institutions in South Africa is the subject of an announcement by the Department of Education in the *Government Gazette* (*Pretoria*) of October 8, 1948. It is understood that State-aided institutions include museums, art galleries and zoological gardens. The members of the commission are Dr. P. J. du Toit (chairman), Dr. G. von Welfligh Eybers, Prof. J. J. Smith, Dr. S. H. Haughton and Dr. S. H. Skaife.

This announcement will be welcomed by South African museum directors generally, but it seems a pity that the scheme could not have been extended to embrace all museums in the Union, for all are faced with similar problems affecting adequate housing accommodation, up-to-date equipment, and staffs trained in modern museum methods and technique. Nevertheless, the present action is a step in the right direction, for the Government has now taken a lead which ultimately may influence all provincial and municipal museums, irrespective of whether they do or do not receive a Government grant.

Generally speaking, there is at the present time a considerable amount of room for the improvement of South African museums in relation to their appeal and use to the general public. Although in one or two of the larger institutions exhibition rooms have been improved by the introduction of the animal habitat group, dioramic backgrounds, and models, etc., museum exhibition in the Union on the whole lacks imaginative construction. In many cases the presentation of collections is along old and stereotyped lines; labelling is often poor and inadequate for purposes of sufficient instruction; related subjects are badly linked—or not linked at all; while some are so scantily treated as to be of little or no value in the museum concerned. Again, the special temporary exhibition of current or topical interest seems to find no place in South African museum administration; and lectures, informal talks, or classes upon subjects of particular interest in the museum do not seem to be a regular, or even frequent, feature of the work of the officials. Introductory series, so useful where the uninitiated and schools are concerned, are usually absent; and very rarely indeed, if at all, are collections used to illustrate or teach such matters as, say, the impact of geology upon the mining and building industries, upon road and railway construction, or upon water-supply, etc.; or again, the impact of biology upon medical and veterinary research, upon agriculture, horticulture, and matters of human health, and so on. The average archæological collection (and most South African museums are rich in this material) neither tells the 'story' of prehistoric man in South Africa nor illustrates archæological method. A great deal more, also, could be effected with the usually abundant collections of native material—in the more graphic portrayal of tribal customs, mode of life and social organisation, for example. The brilliant exhibit of life-like models of Bushmen (both male and female) in the South African Museum at Cape Town well illustrates the possibilities in this direction. These figures, set up in astonishingly realistic attitudes, wear Bushman clothing and carry Bushman weapons of the chase or war, and associated with them are Bushman domestic utensils. Cast from life, these 'living' records of a practically extinct people make the Cape Town Museum unique among all others in the Union.

With few exceptions, the congestion of the average South African museum exhibition-case leaves no room for the treatment of subjects in some of the ways suggested; but considerable improvement would be possible (even without building extensions) if a good half of some of the material exhibited were to be transferred behind the scenes—not to be lost or neglected, but to be suitably and systematically stored for the better use of the student and specialist worker. Several museums, in this way, could make room for better exhibition work in the public galleries.

Other matters which strike one as requiring consideration in the museums of the Union are appointments and retiring ages. At the present time some appointments seem to go to individuals who have already retired from some other walk of life. In the case of directorships or curatorships, especially, it is important that appointments should go to those who have had training and wide experience in museum work and methods, and who can put in a sufficient number of years of service before reaching retiring age. As yet, there seems to be no hard and fast rule as to the age at which a museum official should retire. It is clear, however, that this should be fixed in the interests of any progressive policy of work and service. New ministerial blood at prescribed intervals is a necessity to any institution the primary function of which is public service—and service suitable to the times.

There is, no doubt, a big future for South African museums; in a rapidly developing country they are a cultural necessity. South African museums have already carried out much useful work in scientific research, and vast fields for further study and collection lie before them. As has already been suggested, however, there is room for better work in their educational function, the function which, in the long run, will determine not only their use to the community, but, in addition, their status within it.

J. R. Harding

TWENTY-THIRD ANNUAL CONFERENCE OF ASLIB

During September 17–20, the twenty-third annual conference of Aslib was held at Ashorne Hill, near Leamington Spa. This Conference resumed, for the first time since 1938, Aslib's residential conferences, which, with the fast-expanding number of special librarians and information officers, are essential if the old and experienced members are to mix informally and discuss the difficulties of the younger and comparatively inexperienced information officers. Some idea of the extent to which this is necessary is given by the growth of Aslib's membership: 1,010 on June 30, 1948; 827 in 1947; and 712 in 1946. At the beginning of the War it was less than 300. Of the total, research associations and learned societies account for 33 per cent, industrial and commercial organisations 20 per cent, individuals 22 per cent, overseas members 17 per cent, and British Government Departments 8 per cent. These figures give some idea of the extent to which the information officer and special librarian have become essential members of any well-conducted, modern research establishment and progressive industrial concern.

The report by the director (Miss E. M. R. Ditmas) of the work of Aslib, 1947–48, pointed out that 'Aslib' is now a registered name, and since the amalgamation with the British Society for International Bibliography on January 1, 1948, no longer stands for "Association of Special Libraries and Information Bureaux". The amalgamation added a couple of score of members. The increased amount of work means that a series of afternoon meetings will be held between October 1948 and April 1949, besides the annual conference. Instead, therefore, of an annual publication of *Conference Proceedings*, there will be a new journal, *Aslib Proceedings*.

In March 1948 Aslib called the meeting which is now working towards an Institute of Recorded Sound; sixty students attended the Aslib Study Group in August 1947, and seventy in April 1948, and a memorandum on "Training of Information Officers" was drawn up by a Sub-Committee of the Education Committee; the Information and Library Section recorded 2,521 inquiries, had 66 requests for registered translators and supplied 2,275 items through the Documentary Reproduction Service. The Aslib library receives regularly more than 100 periodicals; but lack of suitable premises makes 52 Bloomsbury Street badly overcrowded. At the request of the Department of Scientific and Industrial Research, Aslib set up, in June 1947, its Committee on the Mechanized Distribution of Information to discuss the uses of mechanization in library and technical information work, and supplied a statement to the Royal Society's Conference. In December 1947 the Committee on the Format and Efficiency of Periodicals was set up.

Naturally, Aslib has taken much part in the documentation work of the British Standards Institution, the British National Committee on Documentation and many international and foreign organisations. Sir Richard Gregory was made an honorary member during the year.

Usually the annual conference of Aslib is organised almost as a symposium of papers on one or, perhaps, two subjects of universal interest. This year it was a miscellaneous collection dealing rather more with the existing problems in the fields of the information officer and special librarian than with the uttering of any startling ideas or announcements.

Saturday morning, September 18, opened with Dr. R. E. Priestley (vice-chancellor and principal of the University of Birmingham) in the chair. Mr. B. Fullman (British Non-Ferrous Research Association, chairman Aslib Education Committee) opened the proceedings on "The Training of the Information Officer", basing his arguments on a statement which had been circulated confidentially to Aslib members. "Information officers," he said, "are fashionable and no home is complete without them, and they are budgeted for as a matter of course." He urged that Aslib should consider issuing a diploma to ensure that organisations would, in the future, obtain properly qualified people. He emphasized how diverse, yet specialized, is the information officer's work compared with that of the librarian as normally considered. He endorsed a flexible arrangement with the Library Association, but emphasized that the scientific world needs information officers and special librarians who have first obtained a science degree.

Mr. J. S. P. Paton (Metropolitan-Vickers) discussed the questionable necessity for the prospective information officer to have to take the whole of the Library Association's course. He pointed out the need for such special requirements as languages, the ability to speak the language of scientific colleagues and for the necessity for good practical experience of research departments.

Mr. F. G. B. Hutchings (Leeds City librarian and chairman of the Education Committee, Library Association) endeavoured to minimize the difference between librarians and special librarians and information officers by emphasizing the amount of inquiry in public libraries and their closer association with local industrial and scientific organisations. He said that the new Library Association syllabus is "getting to be bibliographical rather than literary". Therefore, why a special Aslib diploma and course ?

The lively discussion from the floor emphasized that the industrial and research intelligence officer makes use of information besides collecting and collating, the necessity for the initial scientific training and the fact that ability in this field cannot always be assessed by examination, but is a natural aptitude. It resulted in the whole matter being referred back to the Aslib Council for further consideration after this preliminary airing of many views.

The Saturday afternoon session, under Dr. E. Marsden (New Zealand Scientific Liaison Office, London), was devoted to Prof. J. D. Bernal talking on "The Significance to Special Librarians and Information Officers of the Royal Society's Scientific Information Conference". He opened by stating, "it depends upon Aslib and Aslib members as to whether the resolutions of the Royal Society are implemented". He referred to Dr. D. J. Urquhart's "Survey of Scientific Reading Habits" and gave in some detail the figures and conclusions given in his own paper, "Preliminary Analysis of Pilot Questionnaire on the Use of Scientific Literature" at the Society's Conference. He raised again the necessity for reprints, or 'separates', and the necessity for the relinquishing of copyright by authors of papers, so that they may be freely reproduced from journals. He asked, "Is the liaison between user and the information officer sufficient ?" He mentioned the non-co-ordination between the libraries of scientific institutions in the Bloomsbury area, and how co-ordination had been achieved in his own subject of physics.

Mr. J. E. Cummins (Australian Scientific Research Liaison Office) sketched the library position in Australia, stressing the need for the librarian there to cease "to look upon himself as a keeper of books". Dr. S. R. Ranganathan (president of the Indian Library Association) said that "work in the library world is going on in a casual way without any planning", and called for a special study of 'librometry'. The need for proper co-ordination of abstracting and suggestions that abstracts be available before or as soon as a paper is ready to be read, and not after the now delayed publication, was mentioned in the discussion, in which a large number partook. It emphasized the difficulties and problems of getting the right information to the right person at the right time. The increasing need for this over the years was clearly recognized when Aslib was founded twenty-four years ago to start creating order out of confusion and to be the prime mover ever since.

Sunday morning, under the chairmanship of Mr. J. F. Stanley (British Standards Institution), opened with Mr. Eric Smythe (librarian and research officer of *Reynolds News*) discussing the organisation and working of a newspaper's press-cutting library and the mechanics of storage. He emphasized the speed and efficiency with which such a library should work, and that facts are wanted sometimes on immediate notice five minutes before going to press.

Sir Cuthbert Whitaker, in his fifty-fourth year of editorship of *Whitaker's Almanack*, gave a straightforward account of the "History and Compilation of *Whitaker's Almanack*". He mentioned how his father, the late Joseph Whitaker, while pacing up and down a garden path, in 1868, remembered the "Commonplace Book" he had compiled when conducting the correspondence columns of the *Gentleman's Magazine*. He thought its publication in an organised form, together with meteorological data, which Sir George Airey was delighted to supply, thus justifying the term 'almanack', would be welcomed by the public.

The first *Almanack* for 1869 appeared on December 10, 1868, and had 363 pages and an index of 1,100 entries. The 1948 edition has 1,092 pages and 35,000 references. The plan of the *Almanack* was so carefully designed by Joseph Whitaker that the main part of the work ever since has been "submitting proofs and reducing the exuberance of corrections".

With Dr. J. C. Withers (Shirley Institute) as chairman, Dr. Hugh Clegg (editor of the *British Medical Journal*) and Mr. R. Brightman (Imperial Chemical Industries, Ltd.) talked on "The Art and Technique of Book Reviewing". They both emphasized the importance of a review of a scientific or technical book giving "a clear account of what the book is about, indicating both the scope of the book, the scale on which the subject is treated, and the particular type of reader for whom it is intended". Dr. Clegg strongly advocated that all authoritative book reviews should be signed by the reviewer.

Sunday evening was devoted to a discussion on "Practical Applications of International Collaboration in Documentation", opened by Mr. E. J. Carter (head of the Library Section, Unesco), who said, "It is becoming clearer that documentation and library services are the very roots of international collaboration". It was essential to bring practical people together to collaborate and surmount language difficulties to give complete and efficient transmission of ideas. This means a properly organised and adequate secretariat. "Delegates to international conferences must have documents beforehand in their own language to be able to discuss them with their own people." This was strongly supported by Dr. Ranganathan, who pointed out that many conferences fail because of quite inadequate preliminary documentation. He also advocated that older delegates to conferences should be accompanied by a younger man, who would thus be properly experienced when it became his turn to lead. He emphasized how adequate documentation overcame language difficulties, while the use of a universal classification system, such as the U.D.C., prevented misunderstanding as to the precise definition of a subject. Dr. P. Bourgeois (director, Swiss National Library) pointed out that this was not generally being done, and instanced some recent international conferences, which had achieved little because of the paucity of their practical application of documentation.

Mr. A. B. Agard Evans (Ministry of Works Library) said that there were far too many international resolutions, and not enough practical activity. This was due, in some instances, to the lack of national collaboration first, and he directed attention to the fact that the building industry was one of the wealthiest in the world, yet it had little international collaboration.

In association with the conference, Aslib arranged an exhibition of representative bibliographies and abstracting journals. IVOR B. N. EVANS

INDIAN DAIRY SCIENCE

THE immense importance of a substantial increase in production and consumption of milk and milk products, both to the balance of Indian agriculture and in contributing protein, fat and minerals to the very largely cereal diet of the 320 ± 20 million inhabitants of present-day India is being increasingly appreciated in that country. For perhaps two decades, real efforts have been made to improve the dairy industry in India both as regards milk production (in which Mahatma Gandhi took a personal interest) and as regards milk distribution and manufacture. Progress, hindered by religious as well as economic obstacles, has, however, been rather disappointing.

This slow development has also been due, in no small part, to other causes—paucity of knowledge, the serious shortage of trained dairy husbandrymen and of satisfying opportunities for their activity, the acute lack of dairy scientists, technologists and engineers and the absence of more than a small handful of research workers in dairying. Research is clearly needed in two directions: first, the application to the severer climatic and other conditions of India of the knowledge already applied in the more progressive dairying countries in the temperate zones; and secondly, basic study of the nutrition, breeding and physiology of dairy stock in India and of the microbiology, biochemistry and engineering underlying modern dairying operations.

The recent formation of an Indian Dairy Science Association with similar objects to those of the Society of Dairy Technology in Great Britain, namely, the advancement of dairy science, the provision of opportunities for the exchange of knowledge and ideas, and the encouragement of scientific inquiry into problems arising in the industry, is a step in the right direction. The Association is fortunate in having Sir Datar Singh, the energetic chairman of the Indian Council of Agricultural Research, as its first president. The Association has just issued the first number of a new journal, the *Indian Journal of Dairy Science*, which is to appear quarterly under the editorship of the director of the Indian Dairy Research Institute at Bangalore, Dr. K. C. Sen (Indian Dairy Science Association, Hosur Road, Bangalore, India. 12 rupees per annum).

The present number contains six original articles dealing with aspects of milk production, control of milk keeping quality, milk composition, milk phosphatase, vegetable rennet and indigenous butter. While it would be unfair to apply too critical an eye to some of these early contributions, they are all of value, and one at least, by Krishnamurti and Subrahmanyan, is outstanding. A promising start has been made, and several in Britain who know at first hand of the immense difficulties which have still to be overcome before the mutually dependent partners, dairy science and the dairying industry, can flourish in India, will look forward with great interest to the future progress of this *Journal*.

H. D. KAY

FOREST POLICY IN UGANDA

A STATEMENT on the forest policy for Uganda was recently issued by His Excellency the Governor and published as a Supplement to the *Uganda Gazette* of June 15, 1948.

This statement is of interest as it is promulgated by the Governor himself. The main points are as follows: 1. (i) To reserve in perpetuity, for the benefit of the present inhabitants of Uganda and of posterity, sufficient land (either already forested or capable of afforestation) to maintain climatic conditions suitable for agriculture, to preserve water supplies, to provide forest produce for agricultural, industrial and domestic purposes, and to maintain soil stability in areas where the land is liable to deterioration if put to other uses. (ii) To manage this forest estate to obtain the best returns on its capital value and the expenses of management, in so far as such returns are consistent with the primary aims set out above. (iii) To foster, by education and propaganda, a real understanding among the people of Uganda of the value of forests to them and their descendants. (iv) To encourage and assist the practice of sound forestry by local authorities and private enterprise; and to educate selected Africans in technical forestry.

It is of interest to note that these points in forest policy were first laid down by the Secretary of State for India in London as far back as 1862. They have since been repeated by many governments in many parts of the world, but only rarely have been given practical effect.

The Governor continues: 2. To achieve the first objective of this four-point policy, namely, the creation of an adequate forest estate, the following guiding principles shall be observed: (i) The climatic and physical conditions of the country must be preserved and, if possible, bettered, by first, the reservation of suitable land, and secondly, the maintenance, improvement or re-establishment of vegetation on the most important catchment areas and on other strategic positions. (ii) The supply in perpetuity of the many forms of forest produce required satisfy the wants of the people of Uganda both w and in the future must be assured by the servation, preservation, development and manage- ent of the minimum area of forest land needed for is purpose.

3. It is accepted that the satisfaction of the needs the inhabitants of Uganda must take precedence ver purely financial considerations and the estab- hment of an export trade; and that only when ese needs have been satisfied can the aim of anagement be directed, in production reserves, to taining the greatest revenue compatible with a ntinuous yield, and to promoting an external trade timber and other forest produce.

The statement lays down some general conditions r the implementation of forest policy and the mediate steps to be taken to implement it. In e last paragraph it is said that in the opinion of e Government the primary tasks of the Forest epartment during this decade must be to complete e formation of the forest estate.

The Governor may be congratulated on having rmulated in his statement a true outline of what rest management plans for. In the first thirty ears after the formation of the Indian Forestry epartment in 1864, the formation of the forest tate had to a great extent been completed, it aving been laid down that this was the first object be attained. It is a pity that so many of the lonial forestry services did not undertake this dispensable work during the early years of their nbodiment.

INSTITUTION OF CIVIL ENGINEERS

AWARDS

THE following awards have been announced by the Council of the Institution of Civil Engineers r the session 1947–48:

James Alfred Ewing Medal for 1947: Sir John ockcroft (see *Nature*, April 17, p. 592).

Telford Premiums: B. D. Richards, for his paper n "Tidal Power: its Development and Utiliza- ion"; R. W. S. Thompson, for his paper on "The econstruction of Bamford Filters"; W. J. O. Scott, r his paper on "Roads and their Riding Qualities"; . F. J. Bradbeer and Prof. C. A. Hart, jointly for heir paper on "Photographic Surveying in Relation Road Engineering in Highly-developed Countries"; . V. Blumfield, for his paper on "The Development od Use of Barrel Vault Shell Concrete"; E. A. G. ohnson, for his paper on "Flooding in the Fens and emedial Measures Taken"; W. R. Greathead and . D. Hawkins, jointly for their paper on "First tages in the Construction of the Jan Smuts Airport, ohannesburg"; Dr. S. L. Bey, for his paper on Stresses and Temperature Effects in Dams, with articular Reference to Aswan Dam"; D. H. B. eynolds, for his paper on "The Movement of Water the Middle and Lower Chalk of the River Dour atchment"; F. R. Melville and R. le Geyt Hether- gton, jointly for their paper on "The Pegu Yomas cheme for the Water-Supply of Rangoon"; B. J. horpe, for his paper on "High-Altitude Test Plant: ew Ancillary Services for Testing Engines, Car- urettors, and Aircraft Components under High- ltitude Conditions".

Coopers Hill War Memorial Prize: Prof. A. L. L. Baker, for his paper on "The Heysham Jetty".

Webb Prize: C. E. Dunton and K. Brinsmead, jointly for their paper on "Design, Installation and Maintenance of Long Welded Rails".

Indian Premium: C. G. Sexton, for his paper on "Pre-stressed Reinforced-Concrete Hangar at the Civil Airport of Karachi".

James Prescott Joule Medal and *Miller Prize:* S. Rodin, for his paper on "Site Exploration".

James Forrest Medal and a *Miller Prize:* D. M. Beaton, for his paper on "Coast Protection and Land Reclamation in Holland".

Miller Prizes: S. B. Hart, for his paper on "The Clifton Suspension Bridge"; T. K. George and K. Balasubrahmanyam, jointly for their paper on "The Rational Design of Settlement Tanks"; J. R. Smith, for his paper on "Surveying for Tunnels"; A. R. Goode, for his paper on "Gas Turbines as a Means of Propulsion"; J. D. Harris, for his paper on "Pre-stressed Concrete"; E. Lightfoot, for his paper on "The Open Frame Girder and its Analysis"; R. Franklin, for his paper on "Notes on Surveying from Air Photographs".

Institution Medal and Premium of £10: P. G. Bedson, for his paper on "The Design of Buttress Dams".

Charles Hawksley Prize: J. Black, for his design of a railway station, and a special prize of £50 to J. R. Stanley, for his design of a water tower.

Bayliss Prize: W. E. A. Skinner.

Special thanks of the Institution are accorded to H. J. B. Manzoni, for his paper on "Winter Conditions and the Civil Engineer: Municipal Engineering"; and to W. K. Wallace, for his paper on "Winter Conditions and the Civil Engineer: Railways", who, as members of Council were not eligible for awards.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, November 29

UNIVERSITY OF LONDON (at the Institute of Education, Malet Street, London, W.C.1), at 5.30 p.m.—Prof. E. D. Edwards: "Education for International Understanding—China".*

ENGINEERS STUDY GROUP ON ECONOMICS (at the Central Hall, Westminster, London, S.W.1), at 7 p.m.—Sir John Boyd Orr, F.R.S.: "An Approach to World Government".

ROYAL INSTITUTE OF CHEMISTRY (joint meeting with the WOOLWICH POLYTECHNIC CHEMICAL SOCIETY, at Woolwich Polytechnic, Woolwich, London, S.E.18), at 7.30 p.m.—Mr. M. S. C. Birbeck: "The Electron Microscope".

Tuesday, November 30

UNIVERSITY COLLEGE, LONDON (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. H. E. M. Barlow: "Modern Electric Lighting Technique", I.*

(Second Lecture will be given on Thursday, December 2.)

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Anniversary Meeting.

SIR HALLEY STEWART TRUST LECTURE (at the Memorial Hall, Farringdon Street, London, E.C.4), at 6 p.m.—Mr. Lionel Curtis: "The Atomic Age—The Political Repercussions".*

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS, PHYSICAL METHODS GROUP (in the Chemistry Lecture Theatre, Imperial College of Science and Technology, Imperial Institute Road, London, S.W.7), at 6 p.m.—Annual General Meeting; Mr. R. Donaldson: "The Measurement of Colour".

ASSOCIATION OF BRITISH SCIENCE WRITERS (at Shell Film Theatre, Shell-Mex House, Strand, London, W.C.2), at 7 p.m.—Lecture on "The Scientific Film".

INSTITUTION OF THE RUBBER INDUSTRY (at Caxton Hall, Caxton Street, London, S.W.1), at 7 p.m.—Mr. T. R. Dawson: "Lignin".

Wednesday, December 1

UNIVERSITY OF LONDON (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5.15 p.m.—Dr. J. W. Trevan: "Statistics from the Standpoint of a Pharmacologist".* (Further lecture on December 8.)

Institution of Electrical Engineers, Radio Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. P. R. Coursey: "Fixed Resistors for use in Communication Equipment, with special reference to 'High Stability' Resistors".

Linnean Society of London (in conjunction with the Systematics Association, at Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Demonstration: "Taxonomy up to and including Linnæus".

Manchester Metallurgical Society (at the Engineers' Club, Albert Square, Manchester), at 6.30 p.m.—Mr. F. Fancutt and Mr. J. C. Hudson: "The Protection of Iron and Steel against Corrosion".

Institute of Welding, Manchester and District Branch (in the Reynolds Hall, College of Technology, Manchester), at 7 p.m.—Mr. C. Schofield: "Fabrication of Resistance Welding".

Society of Public Analysts and other Analytical Chemists (joint meeting with the Food Group of the Society of Chemical Industry, at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 7 p.m.—Discussion on "Food Standards and Labelling".

Society of Chemical Industry, Plastics Group (joint meeting with the Northern Ireland Section, at the Royal Belfast Academic Institution, Belfast), at 7.30 p.m.—Dr. R. G. R. Bacon: "Some Chemical Aspects of Plastics Manufacture".

Thursday, December 2

Chadwick Public Lecture (at St. Mary's Hospital Medical School, Norfolk Place, Praed Street, London, W.2), at 4.30 p.m.—Dr. C. Seeley: "Preventive Medicine and Clinical Medicine in relation to the Public Health" (Malcolm Morris Memorial Lecture).*

Chemical Society, Liverpool Section (joint meeting with the Local Sections of the British Association of Chemists, the Royal Institute of Chemistry and the Society of Chemical Industry, at the University, Liverpool), at 4.30 p.m.—Sir John Lennard-Jones, F.R.S.: "Modern Theories of Chemical Valency".

Institution of Mining and Metallurgy (at Film House, Wardour Street, London, W.1), at 5 p.m.—Film on "Atomic Physics".

Institution of Electrical Engineers (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. A. G. Milnes: "Magnetic Amplifiers"; Mr. H. M. Gale and Mr. P. D. Atkinson: "The Theory and Design of Magnetic Amplifiers".

University of London (in the Chemistry Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. E. D. Hughes: "The Kinetics and Mechanism of Reactions" (Inaugural Lecture).*

Chemical Society, Sheffield Section (joint meeting with the Local Section of the Royal Institute of Chemistry and the Sheffield University Chemical Society, in the Chemistry Department Lecture Theatre, the University, Sheffield), at 6 p.m.—Sir Wallace Akers: "Problems in the Production of Useful Power from Nuclear Energy".

Royal Aeronautical Society (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6 p.m.—Mr. G. R. Edwards: "Problems in the Development of a New Aeroplane".

Leeds Metallurgical Society (in the Chemistry Department, The University, Leeds), at 7 p.m.—Dr. J. Ward: "Recent Developments in Photoelasticity".

Royal Institute of Chemistry (at Acton Technical College, High Street, Acton, London, W.3), at 7.30 p.m.—Dr. N. Booth: "Careers for Chemists".

Society of Chemical Industry, Chemical Engineering Group (joint meeting with the Bristol Section of the Society of Chemical Industry, in the Chemistry Department, the University, Bristol), at 7 p.m.—Dr. Katherine Williams: "The Physiological Effects of the Products of Nuclear Fission".

Friday, December 3

Chemical Society, Glasgow Section (in the Royal Technical College, Glasgow), at 2.15 p.m.—Scientific Papers.

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.15 p.m.—Dr. H. R. Ing: "The Pharmacology of Homologous Series".*

Geologists' Association (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Prof. H. H. Read, F.R.S.: "International Geological Congress, London, 1948".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. F. E. Zeuner: "Time in Evolution".

Saturday, December 4

Biochemical Society (at the Middlesex Hospital Medical School, London, W.1), at 11 a.m.—Scientific Papers.

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 2.30 p.m.—Dr. Reginald Le May: "The Ancient Monuments of Cambodia, including Angkor".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer in Physics—The Principal, Acton Technical College, High Street, Acton, London, W.3 (December 4).

Lecturer in Textiles at Coventry Technical College—The Director of Education, Council House, Coventry (December 4).

Assistant Lecturer in Pharmaceutical Chemistry at Bradford Technical College—The Director of Education, Town Hall, Bradford (December 4).

Editor—The General Secretary, Chemical Society, Burlington House, Piccadilly, London, W.1 (December 4).

Vice-Principal (Ref. G.479/48A) and Assistant Lecturers Ref. G.480/48A) for the West Sussex County Agricultural Executi Committee's Agricultural Training Centre at Brinsbury, Pulborough The Ministry of Labour and National Service, Technical and Scient Register (K.), York House, Kingsway, London, W.C.2, quoting t appropriate Ref. No. (December 4).

Assistant Lecturer in Geography—The Secretary, Lond School of Economics, Houghton Street, Aldwych, London, W.C (December 6).

Senior Lecturer in Agriculture (with special qualifications Crop Husbandry and with teaching experience)—The Registrar, T University, Leeds 2 (December 6).

Junior Assistant Physicist in the Clinical Physics Depar ment—The Secretary and House Governor, Mount Vernon Hospi and the Radium Institute, Northwood, Middx. (December 8).

Statisticians in various Government Departments—The Secreta Civil Service Commission, 6 Burlington Gardens, London, W.1, quoti No. 2316 (December 11).

Candidate with a research degree and qualification in chemi engineering (Ref. TT/107), and a Candidate with chemical engineeri qualifications and considerable research experience (Ref. TT/10 for two appointments in the Central Research Establishment of t National Coal Board at Stoke Orchard, Cheltenham—The Natio Coal Board, Establishments (General) Branch, Hobart House, Gr venor Place, London, S.W.1, quoting the appropriate Ref. N (December 13).

Deputy Director and Senior Lecturer in the Department Chemical Pathology—The House Governor, St. Mary's Hospi and Medical School, Paddington, London, W.2 (December 13).

Departmental Demonstrator in Geology and Petrology The Professor of Geology, University Museum, Oxford (December 1

Senior Research Officer (Ref. No. 1987), a Technical Secreta (Ref. No. 1988), and five Research Officers (Ref. No. 1989), the staff of the Coal Survey Section of the Council for Scientific a Industrial Research, Sydney—The Chief Scientific Liaison Offic Australian Scientific Research Liaison Office, Africa House, Kingswa London, W.C.2, quoting appropriate Ref. No. (December 18).

Lecturer in Biochemistry, a Demonstrator in Biochemistr and a Demonstrator in General Physiology—The Registr University College of South Wales, Cathays Park, Cardiff (Decemb 18).

Professor of Physics, and a Lecturer in Bacteriology, in t University of Queensland—The Secretary, Association of Universiti of the British Commonwealth, 32 Woburn Square, London, W.C (December 31).

Senior Lecturer or Lecturer in Mathematics, and a Seni Lecturer or Lecturer in Physical Chemistry, in the Universi College of the West Indies—The Secretary, Inter-University Coun for Higher Education in the Colonies, 8 Park Street, London, W (February 15).

Mycologist as *Oidium* Research Officer to the Rubber Resear Scheme, Ceylon—The Secretary, London Advisory Committee f Rubber Research (Ceylon and Malaya), Imperial Institute, Sou Kensington, London, S.W.7 (February 28).

Lecturers (2) in the Department of Physics, Sunderland Tec nical College—The Director of Education, Education Offices, 15 Jo Street, Sunderland.

Chemist (Scientific Officer grade) for fundamental research physical chemistry of metal systems at higher temperatures, and Research Assistant for work on physical chemistry of metal syste in which radioactive tracer techniques are employed—The Person Officer, British Iron and Steel Research Association, 11 Park La London, W.1.

Lecturer in the Department of Chemistry and Biology—T Registrar, Municipal College, Portsmouth.

Research Technician in the Dental School—Prof. Matthew The University, Manchester 13.

Physical Chemists (Senior Scientific Officer and Scientific Offic grades), an Organic Chemist (Scientific Officer grade), Chemis (Experimental Officer grade), a Chemical Engineer (Scientific Offic grade), and Engineers (Experimental Officer grade), in a Minist of Supply research and development establishment in Lancashire The Ministry of Labour and National Service, Technical and Scienti Register (K.), York House, Kingsway, London, W.C.2, quoti F.936/48A.

Editorial Assistant for the *Journal* of the Institution—T Secretary, Institution of Electrical Engineers, Savoy Place, Victo Embankment, London, W.C.2.

Honours Graduate in Physics or Electrical Engineerin to assist in the further development of a 2 million volt electrosta generator and to co-operate in radiobiological research using t neutrons and X-rays from this machine—The Director, Radi therapeutic Research Unit, Hammersmith Hospital, Ducane Roa London, W.12.

Educational Psychologist—The Chief Education Officer, Educ tion Office, Warrior Square, Southend-on-Sea.

PROFESSIONAL STATUS OF THE BIOLOGIST

ONE of the paradoxes of civilized life is the lowly position occupied among the sciences by the study of living things. There seems, in Great Britain at least, to be a general disposition to regard biology as something in the nature of a pastime, while the physicist and the chemist are held in respect as serious practitioners. Only in the treatment and, to a modest degree, the prevention of disease, and in agriculture, has biological science a recognized position. That the well-being of the human race is closely bound up with the ineludible facts of life, which together constitute the equilibrium of Nature, is not generally recognized.

It was, therefore, with special interest that we studied the presidential address of Sir Henry Tizard at the recent meeting in Brighton of the British Association, and especially his conclusion that "Whatever new comforts and luxuries may be provided in future by the advancement of physical science, it is on the development of the biological sciences that the peace and prosperity of the world will largely depend". With this view we are in hearty agreement, though we should prefer to substitute for the word "largely" the word "ultimately". Sir John Boyd Orr expounded a similar view when addressing the Summer School in 1942 of the British Social Hygiene Council held in Cambridge.

But, if biology is to play the part required of it, it must be recognized as a profession, not as a hobby. It must be placed on the same professional level as chemistry, physics, engineering and medicine, with a corresponding prestige. For this reason we welcome the announcement, referred to on p. 878, of the proposal to establish an Institute of Biology. The other sciences to which we have referred have their professional organisations competent to give advice on questions involving the training, employment and remuneration of its members. Biology has no such comprehensive organisation, and, in consequence, many of those who wish to be recognized as professional biologists are led to refer to their membership of one of the academic societies, which does not necessarily involve, and is commonly quite independent of, professional qualifications. A notorious example of this practice is the use of the letters F.Z.S., which has compelled the Council of the Zoological Society of London to introduce a rule requiring all candidates for election to sign a declaration that they agree not to use these letters in furtherance of business interests.

Apart from being of real benefit to the individual biologist, an Institute of Biology would be a valuable, indeed an essential, asset to Great Britain and the British Commonwealth. On biological progress depends much that is inherent in the plans for the development of the Colonies, for example. Young biologists who take their first posts abroad in a British Colony frequently find themselves cut off from important biological contacts. An Institute could help such men in many ways, and could keep records of their service; then, in the event of their appointment being terminated for, say, political reasons (as has happened in India, Burma and Palestine), the Institute would be available for helping these men to find appointments elsewhere which are commensurate with their records, experience and qualifications.

It has been suggested that it may prove difficult to form an Institute of Biology because of the acute jealousies and antagonisms to which this field of science has appeared to give birth, and the consequent difficulty of persuading any group of biologists to agree on a common policy. It is to be hoped that such reasons will not adversely affect the final outcome; for it is quite clear that an Institute of Biology is badly needed in Britain. Moreover, coming from the Biological Council, the proposal presumably has the support of the leading biological societies and associations in Britain; these are listed at the end of the article already referred to. The founding of an Institute should be the main objective of all recognized biologists; its constitution, aims and objectives will have to be thrashed out around the conference table afterwards.

MICROWAVE TECHNIQUES

Microwave Transmission Circuits

Edited by George L. Ragan (Massachusetts Institute of Technology: Radiation Laboratory Series, No. 9.) Pp. xvii+725. 51*s*.

Technique of Microwave Measurements

Edited by Assoc. Prof. Carol G. Montgomery. (Massachusetts Institute of Technology: Radiation Laboratory Series, No. 11.) Pp. xix+939. 60*s*.

Crystal Rectifiers

By Assoc. Prof. Henry C. Torrey and Assoc. Prof. Charles A. Whitmer. Edited by S. A. Goudsmit, James L. Lawson, Leon B. Linford and Albert M. Stone. (Massachusetts Institute of Technology: Radiation Laboratory Series, No. 15.) Pp. xiii+443. 36*s*.

Microwave Mixers

By Robert V. Pound; with a Chapter by Eric Durand. Edited by C. G. Montgomery and D. D. Montgomery. (Massachusetts Institute of Technology: Radiation Laboratory Series, No. 16.) Pp. xii+381. 33*s*.

Microwave Receivers

Edited by Assoc. Prof. S. N. Van Voorhis. (Massachusetts Institute of Technology: Radiation Laboratory Series, No. 23.) Pp. xviii+618. 48*s*.

(New York and London: McGraw-Hill Book Co., Inc., 1947–48.)

As readers of these columns will be aware, workers in the Radiation Laboratory of the Massachusetts Institute of Technology are producing a series of books on microwave techniques which, when complete, will contain twenty-eight volumes, one of which is to be an index of the whole series. Reviews of several books of the series have already appeared in *Nature*, and the present notice deals with a further six volumes, namely, numbers 9 11, 14, 15, 16 and 23.

According to the general foreword to the series the aim has been to make widely available, as soon as security regulations permitted, the results of the enormous research and development effort on radar and related techniques which took place during the Second World War. It is further stated that: "The work described is the collective result of work done at many laboratories, Army, Navy, university, and industrial, both in this country [that is, United States of America], and in England, Canada and other Dominions".

It would be easy to criticize each one of these volumes in detail, and to point out faults here and there in matters of presentation, to suggest that some things might have been better said and that some might with advantage have been left out, or that there is an unnecessary amount of duplication of materia between volumes. Nevertheless, if all this were done, one must still be full of admiration for the manner in which such a great task has been accomplished in so short a time, and, with all its faults on the whole so successfully. It might also be said that some of the techniques described are already out of date; but that is inevitable in a subject which has developed as rapidly as has the study of microwave phenomena in the past few years. It must be said, however, that despite the statement in the foreword, most of the work described in detail is o American origin, and that, with a few notable exceptions, references to British work are infrequent This is probably not due to any ulterior motive on the part of the various authors, but simply arises from the fact that much British material which might, and could otherwise, have been used had not been 'declassified', and so was not available for reproduction at the time these books were written.

The duplication of a certain amount of subject matter in several volumes is perhaps inevitable since the whole field has been split up into so many parts and some of these naturally overlap. On the othe hand, in reading any given volume one may occasionally be aware of certain gaps in the presentation for, in the process of the development of each book subjects more properly dealt with in one of the companion volumes are touched upon. A certain amount of cross-reference from volume to volume is therefore necessary; if this were not to be expected the degree of duplication would become even more marked.

Volume 9, entitled "Microwave Transmission Circuits", is concerned with the problem of the transmission of power at microwave frequencies from one place to another. In the course of some 700 pages many aspects of this problem are dealt with in very great detail. Most of the designs described in these pages were developed in the war-time Radiation Laboratory of the Massachusetts Institut of Technology, though workers in this field in Grea Britain will recognize many features which could just as well have been described as originating here In the first two chapters a discussion of conventiona transmission-line theory leads to a treatment of th guided wave concept, and of the more common type of wave-guide. There then follow chapters dealin with such subjects as materials and construction techniques, rigid and flexible coaxial lines and wave-guides, coupling units and rotary joints in transmission systems. Tuners, power dividers and switches are described in Chapter 8. The last two chapters, 9 and 10, are devoted to a discussion of microwave filters, the first from a theoretical and the second from a design point of view. The principles of filter theory put forward here are not merely extensions to microwave frequencies of principles already in use at lower frequencies; they represent rather a significant contribution to the subject along entirely new lines, and the results should find many useful applications in the design of filters for low frequencies.

Many readers will probably find Volume 11, on the "Technique of Microwave Measurements", one of the most valuable in the series, in that it contains much that will continue to be of great use over the whole field of microwave applications in the future. Throughout the book, in the consideration of the design and construction of equipment for microwave measurements, one is continually reminded that it is here necessary to think in terms of the electromagnetic field rather than in terms of current and voltage, the usual practice at lower frequencies. The volume is divided into four main parts in which are described power generation and measurement, wave-length and frequency measurements, the measurement of impedance and standing waves, and finally attenuation and radiation measurement. There are fifteen chapters, and the topics treated in detail include microwave oscillators and devices by means of which their frequency may be stabilized, measurement of radiofrequency power at low, medium and high levels, and the design of signal generators and noise sources. In Part 2 the use of wave-guides and cavity resonators in the measurement of wave-length and frequency is described, and also the determination of pulse shape and associated frequency spectrum. Part 3 contains a description of the measurement of standing waves and the use of various types of impedance bridge. Part 3 further includes a long and interesting chapter (Chapter 10) in which methods of determining dielectric constants are discussed, and one is pleased to note here considerable reference to British work. The final part of this volume (Chapters 11–15) deals with the construction of such items of apparatus as microwave attenuators, both of the wave-guide 'cut-off' and resistive types, and directional couplers. There are also chapters on the measurement of attenuation and on radiofrequency phase and pattern determinations.

"Microwave Duplexers", Volume 14, is of rather more specialized interest than the two books discussed above. It is concerned largely with the design and behaviour of switching devices which enable a common aerial system to be used for a high-power transmitter and a receiver, and which are therefore of fundamental importance in the construction of radar sets. The characteristics of these switches at both low- and high-power levels are discussed, the high-power level operation being dealt with in considerable detail; and the properties of various gases which are used in the switches are described. The final chapter (9) includes a description of techniques whereby a measurement of the performance of the switches, as well as of the duplexer as a whole, may be made. These special switches were a war-time development, and naturally the only thing of importance at that time was that they should work; much of the knowledge we have of them is still of an empirical nature. Chapter 5 is, however, devoted to a theoretical treatment of the gaseous discharge at very high frequencies. This is admittedly a most difficult subject—our understanding of the phenomenon even at lower frequencies is still incomplete—but the author presents much that is known in a very satisfactory manner.

"Crystal Rectifiers" is the title of Volume 15, and in this book we see how an early radio component, which has been but little used since the invention of the thermionic valve several decades ago, has once again become an important element in microwave equipment. The crystal rectifier is now compact and stable, and is superior to the thermionic diode in many applications. Its most extensive use so far in the new field has been as a frequency converter in microwave receivers, where its performance is unequalled, and also as a low-level detector. Volume 15 is divided into three main parts, the first of which deals with the general fundamental properties of the crystal rectifier, and in Chapters 3 and 4 we have an extensive treatment of the theory of semi-conductors and point-contact rectifiers. These two chapters include a discussion of such subjects as electron distribution in semi-conductors, work functions and contact potentials, conductivity and Hall coefficients, barrier-layer rectification, formation and structure of the barrier layer, depletion layers and rectification at very high frequencies. It is well known that the theory of many of these phenomena is as yet far from complete, and no attempt is made to disguise this fact in the present treatise or to gloss over experimental results which are not in accordance with the theory as it now stands. Part 2, comprising Chapters 5–10, deals with the crystal as a frequency converter and continues with a discussion of noise generation in crystals, of loss and noise measurements, of the theory and experimental information on the burn-out of crystals, test equipment for the measurement of conversion-loss and noise, and finally manufacturing techniques. All the examples given, and nearly all the manufacturing processes quoted, are American. 'Special types' are described in Part 3 (Chapters 11–13). The properties of crystal rectifiers used for detection at low power-levels are considered in Chapter 11, while Chapters 12 and 13 are concerned with a study of high-inverse-voltage rectifiers and welded-contact germanium crystals. Many would probably say that some of the types discussed should no longer be regarded as 'special'.

The volume on "Microwave Mixers" (No. 16) necessarily duplicates a certain amount of the material of Volume 15, since it deals mainly with the use of the crystal as a frequency converter in superheterodyne radar receivers. After an introductory chapter, therefore, in which there is a classification and description of types of microwave receiver, and Chapter 2, which contains a treatment of the physical characteristics of crystals and of network equivalences for crystal mixers, the emphasis in the succeeding chapters is almost entirely on the design and construction of mixer circuits and on allied problems. Simple microwave crystal mixers for the centimetre-wave band are described in Chapter 3, and multiple-function mixers in Chapter 4. Then follow chapters on local-oscillator noise and on balanced mixers, including some discussion on the characteristics and uses of the 'Magic-T'. Chapter 7 contains a description of various types of frequency-control circuit, and the last chapter (8) deals with special measurement techniques for such properties as noise-figure and admittance loss of mixers.

The subject-matter of Volume 23 is "Microwave Receivers". Here again we find a certain amount of duplication, particularly with Volumes 14 and 16, since duplexers and mixers are naturally associated with receivers, but it is not so extensive as to prove irksome. One might, however, have expected a more logical arrangement of the subjects treated in the early chapters. Duplexers, microwave mixers and local-oscillators are dealt with briefly in Chapter 2—local-oscillators, in fact, too much so. Chapters 3, 4, 5 and 6 are concerned with automatic frequency-control systems, intermediate-frequency input circuits, very high frequency amplifiers, mixers and oscillators, and intermediate-frequency amplifiers respectively. Second detectors are described in Chapter 7, video-amplifiers in Chapter 8 and gain control circuits in Chapter 9. There are then three chapters on the mechanical construction of receivers, radiofrequency and intermediate-frequency test equipment. Chapters 13–17 give details of the design and construction of several specific receivers, including an airborne centimetre wave-length type, an automatic tracking radar, a two-band 200 Mc./s. superheterodyne receiver and a wide-band frequency-modulation receiver. In the last four chapters, 18–21, there is a more general discussion of beacon superheterodyne receivers, crystal-video receivers, supergenerative receivers and, finally, moving-target indication systems. It might, perhaps, have been better to sacrifice a little of the extensive detailed treatment of the intermediate- and video-frequency circuits for a rather more comprehensive account of the radiofrequency aspect of the problem, since this seems to have been passed over all too briefly. Of the six volumes here discussed the present reviewer found this one perhaps the least satisfactory in the matter of general presentation and balance of subject-matter.

There are remarkably few typographical errors in all of these volumes despite the conditions of speed under which they must have been prepared. They are all further characterized by a great wealth of circuit diagrams, line drawings and, in many instances, by photographs of equipment. These features will be welcomed by, and will be of great value to, anyone wishing to design and construct microwave equipment, and to such—or indeed anyone interested in microwave techniques—these books may certainly be recommended. J. A. Saxton

POPULAR BOTANY

The Growing Plant

By Prof. W. Neilson-Jones. Pp. 206+8 plates. (London: Faber and Faber, Ltd., 1948.) 16*s*. net.

The popularization of science has become an important social activity. Unesco holds conferences on how it should be done; and the Russians have a special government department to manage it in the Soviet Union. The public demand for it is sufficient to support numerous books on popular science, and recurrent publications such as *Science News* and *New Biology*. Already the difference between books on science and books on popular science has become indistinct: there is continuous variation, from the monograph by a specialist for a few specialists, to the article by a journalist for a million newspaper readers. There is an increasingly important demand for books lying between these two extremes, for the reader who knows some science already. This sort of reader is not easy to satisfy. He does not want catalogues of 'wonders of Nature'; he is annoyed if he is mystified; and he demands a high standard of accuracy. The journalist who has 'cashed in' on the popularity of science cannot write popular science at this level; it must be done by a professional scientific worker, and it is exasperatingly difficult.

Prof. W. Neilson-Jones is to be congratulated on having written a book which will go a long way toward satisfying the reader who is already familiar with some science. His book is (as one would expect) accurate, though many botanists will disagree with some of his views on vernalization and photoperiodism. It is written in an easy (though occasionally ambiguous) style, with a pleasant dry wit. It is a series of independent essays on some aspects of botany which are not treated well in elementary text-books: the plant as informant, chimæras, plant hormones, the control of flowering, plant nutrition, and the story of the soil. The book contains much of what our grandfathers called 'curious information': the difficulties in making floral clocks, the use of tomatoes to locate escaping gas, the occurrence of daisies on prehistoric trackways, and so on. However, the author does not try to impress the reader by means of staggering statistics or arresting adjectives, and he draws his examples from a life-time of experience and thought.

On the dust cover it is said that the book is for the general reader; but it would be unfair on the book to judge it by this criterion. It is rather an anthology of what a botanist thinks will interest other scientific workers. He would be a hardy general reader who could read comfortably that "the fully oxidised tetravalent form of manganese" is not available to plants, and that "no plastids from the pollen grains are brought into the egg cell at fertilization". However, as a book for the science master, the chemist whose hobby is gardening, the horticulturist, the first-year student, the reader (in brief) of *New Biology* and *Science News*, "The Growing Plant" can be recommended with confidence. The book is well produced and well illustrated, although there is an unaccountable transposition of words on page 19. E. Ashby

CONGRESS OF BIOLOGICAL CHEMISTRY

Un symposium sur les proteines

Par A. Tiselius, D. P. Riley, E. Gorter, D. G. Dervichian, M. Joly, J. Brachet, P. Rebuffat, R. Vendrely, C. Wunderly, V. Desreux, H. Dieu, M. Dubuisson, J. Jacob, E. J. Bigwood, M. Jutisz, E. Lederer, G. Hamoir, P. Desnuelle, M. Rovery et M. Errera. (Médecine et biologie, Monographies publiées sous la direction de Marcel Florkin, No. 5.) Pp. 284. (Liége: Éditions Desoer; Paris: Masson et Cie., 1947.) 165 francs.

The Seventh Congress of Biological Chemistry was held at Liège in October 1946. It was thus the first large international gathering of biochemists to be held in Europe after the War. The collection of seventeen papers, contributed to the general discussion on proteins, has now been published under the title "Un symposium sur les proteines". It is of particular interest to the general reader in chemistry and biochemistry since it reveals trends of thought that are forming the background for the present remarkable developments in experimental technique.

The subject-matter of the opening paper by A. Tiselius was happily chosen in that it served as a logical introduction to many of the later contributions to the discussion. Prof. Tiselius dealt with the general strategy of the attack on a problem that has long intrigued chemists, biochemists and physicists interested in proteins, namely, that of the detailed orientation of the amino-acid residues in the protein molecule. The logical way of attacking this problem is by a process of successive fragmentation of the protein chain. If large fragments could be isolated, they could again be broken up into smaller fragments, the constitution of which could be determined by methods already available. The problem is, of course, mainly one of technique, but, as further contributions to the discussion showed, a rich field is developing in the isolation, determination and synthesis of oligopeptides and polypeptides; and although it may be too much to hope that the complete constitution of a natural protein will be determined in the near future, it is clear that a concerted attack on these lines by the many workers already engaged would yield an understanding of the main features of protein structure.

Another important aspect of the problem is the study of the natural protein molecule as a whole, since it is clear that no real advance can be made by the method of successive degradation until adequate proof is available that the protein is, in fact, a single molecular species. The importance of this point is now well appreciated, and the newer physical and chemical methods are increasingly employed in the search for protein preparations of proved molecular homogeneity. This search is proving more difficult and more prolonged than was at one time expected, and several of the papers, reporting studies of proteins by use of X-ray diffraction, electrophoresis, and the spreading of layers on water, emphasized the extreme complexity concealed by the terms 'albumin' and 'globulin'.

THE MIND OF THE CHILD

Childhood and After

Some Essays and Clinical Studies. By Dr. Susan Isaacs. Pp. viii+245. (London: Routledge and Kegan Paul, Ltd., 1948.) 15*s.* net.

THIS volume of selected papers, nearly all of which have already appeared in journal form, furnishes a representative sample of the late Mrs. Isaacs' contributions to the theory and practice of child psychology during the past twenty years [see p. 881]. The contents comprise five papers dealing with general aspects of child welfare and eight of a more specialized nature devoted to problems in the field of psycho-analysis. The general papers include a competent review of recent advances in the psychology of young children, an essay on the mental hygiene of the pre-school child and a discussion of the educational value of the nursery school. Included also is a report dealing with the question of children in institutions, originally presented as a memorandum to the Home Office Care of Children Committee in 1945 and here printed in full for the first time. Although some may feel that the arguments advanced in this report are based on a somewhat selective consideration of the evidence, their cogency can be denied by none who has to do with the institutional care of young children. The memorandum is a model of lucid presentation and persuasive discussion of a difficult problem.

The eight technical papers which make up the bulk of the volume will probably prove of greater interest to the scientific reader. Four deal with theoretical aspects of psycho-analysis and four with special aspects of child development considered from the psycho-analytic point of view. Much of the material discussed may appear bizarre, if not wholly improbable, to the reader unversed in Freudian psychology. It must, however, be borne in mind that the evidence in favour of what Freud called (rather misleadingly) infantile sexuality is nowadays extremely impressive. Although there is disagreement on points of detail, the broad principle of early psycho-sexual development is accepted by a great many psychologists outside the Freudian fold. This principle not only renders comprehensible a wide variety of psychoneurotic manifestations but also contributes in an important way to our understanding of the normal processes involved in the formation of character. One must, therefore, expect of the reader at least some understanding of the Freudian position if he is to follow the arguments developed in these papers. If he remains unconvinced of its basic validity, he would do better to turn to Freud's original writings than to persevere with a book such as this.

A striking impression which is left on the reader of these papers is the virtual impossibility of understanding the mind of the child in terms of adult psychology. Although we have long outgrown anthropomorphism in the biological field, something very like it appears to cling to us in our conceptions of the child's mentality. From the work of Mrs. Isaacs and other child analysts, we realize the futility of attempting to interpret the mind of the young child in terms of the attitudes and beliefs of adult life. The mind of the child, it appears, is a mind in which impulses of a primitive nature give rise to a wealth of phantasies, in part unconscious, which are apt to mingle freely with the world of sense perception. In this phantasy world, figures derived from the parents acquire qualities of beneficence or punitiveness out of all proportion to the child's actual experience. These phantasies not only influence the child's acquisition of conscience and character but also may lie behind a variety of psycho-neurotic manifestations. Their significance in relation to aggression and guilt, 'temper tantrums' and anxiety, is well brought out by Mrs. Isaacs in her clinical studies.

It must be mentioned that the author of this book, in common with so many protagonists of psycho-analysis, pays scant respect to the constitutional factor in neurotic illness. Although Freud himself admitted that all neurosis is at bottom a constitutional affair, this aspect is constantly neglected in neo-Freudian psychopathology. In this connexion, the medical reader will not be slow to note that several of Mrs. Isaacs' patients displayed pre-psychotic manifestations. The latter surely betray a constitutional element which cannot be neglected in theoretical interpretation. One might suggest that until the organic basis of psycho-neurotic illness is more fully considered by psycho-analysts, much of their doctrine will remain, in Freud's words, ". . . but a superstructure which will have to be set on its organic foundation". O. L. ZANGWILL

ROYAL SOCIETY

ANNIVERSARY ADDRESS BY SIR ROBERT ROBINSON, F.R.S.

On behalf of the Fellows of the Royal Society the following telegram was sent on November 16 to His Majesty the King: "Your loyal and dutiful subjects the President, Council and Fellows of the Royal Society of London beg leave to offer our respectful and sincere felicitations on the birth of the Prince".

A message was also sent to Her Royal Highness the Princess Elizabeth, as follows: "The President, Council and Fellows of the Royal Society of London send their respectful and sincere congratulations to Your Royal Highness on the happy event of the birth of the Prince".

We have received gracious acknowledgments in the following terms: "Please convey to the Council and Fellows of the Royal Society the sincere thanks of the Queen and myself for their kind message on the birth of our grandchild.

"George R."

"We are most grateful for your kind message of congratulations.

"Elizabeth and Philip"

AWARD OF MEDALS, 1948

Copley Medal

The **Copley Medal** is awarded to Prof. Archibald Vivian Hill, for his outstanding contributions to the physiology of muscular processes.

Towards the end of the nineteenth century physiologists discerned a field of investigation in the physical and chemical phenomena involved in the characteristic activity of muscle and nerve; but the questions propounded could receive no satisfactory answers, chiefly owing to the lack of adequate methods. Hill, during the last thirty-five years, has applied profound mathematical skill and a flair for the design and management of delicate instruments to the provision of a sound basis for experimental and theoretical advance. In his hands the thermopile was developed into an instrument of great precision and delicacy, and conditions for its use in relation to the material studied were established so as to provide significant results.

The work on heat production in muscle has led to a picture within a framework which can accommodate many contemporary biochemical studies in a harmonious fashion. Attention has constantly been paid to ensuring the thermodynamic soundness of the systems suggested. Moreover, he was able to exploit some of his findings on isolated muscle in the course of a study of the dynamics of muscular contraction in the living body, including that in the human subject.

A natural extension of Hill's researches has enabled him to contribute notably to our knowledge of the heat-production and excitability of nerve. Previous workers failed to detect any heat-production in nerve tissues, but Hill demonstrated the definite thermal changes that are associated with the passage of impulses. These were found to be so small that no one-way contemporary chemical reaction could account for them. It would be necessary to postulate reversible changes which proceed in both directions. This was a main factor in the elaboration of the modern view that the nerve impulse results in an altered state of polarization of the essential surface membranes. The heat change which occurs after the passage of the impulses was found to be small but definite, and was related to the energy expended in the recovery of the membrane.

Hill has made contributions of great distinction in other fields, and among other topics investigated by him is that of the physical chemistry of the oxyhæmoglobin equilibrium in the blood.

Hill has been a source of inspiration to many pupils, collaborators and colleagues, and has founded a school of research. His eminent services to physiology have been possible as the result of a happy combination of wide basic knowledge of the physical sciences, unusual skill in the design and execution of experiments, a philosophic outlook, and above all the curiosity and ambition to attack some of the most difficult problems in biophysics and biochemistry.

Rumford Medal

The **Rumford Medal** is awarded to Prof. Franz Eugen Simon for his distinguished researches on the properties of matter at low temperatures.

The school of low-temperature physics which Simon has created at Oxford is one of the leading centres of such research in the world and has achieved highly important results in the spheres of both theory and practice.

His great knowledge of thermodynamics was brought into service in the development of extremely simple methods for reaching the temperatures of liquid helium in the laboratory. He realized that at low temperatures adiabatic expansion of helium compressed into a small reservoir would absorb sufficient heat to liquefy the bulk of the gas and to cool the container and specimens under examination to liquid helium temperatures. Thus, provided reasonable supplies of liquid air are available, it becomes possible for any laboratory to carry out investigations at the lowest attainable temperatures with equipment which is inexpensive and simple to operate. Many other contributions to technique in this field have been made by Simon and his co-workers.

With the aid of these new or improved methods many interesting observations, with a bearing on fundamental knowledge, have been made. Outstanding problems in superconductivity, especially the part played by impurities, have been solved and the 'freezing out' of magnetic flux has been explained. The peculiar properties of liquid helium II and the transition to this state have been investigated intensively. The thermodynamics of the approach to absolute zero has been stated very clearly by Simon, and progress has been made in new methods for reaching this temperature. More recently, extended equipment has facilitated the study of the properties of atomic nuclei oriented in magnetic fields.

Simon has made significant contributions to the elaboration of devices for the separation of isotopes and to the design of plants in which thermodynamic considerations are of predominating importance.

He has aptly illustrated the thesis that, in the world of modern physics, discovery and the progress of theory follow surely on the introduction of new and powerful tools of research.

Royal Medals

A ROYAL MEDAL is awarded to Prof. Harold Jeffreys for his fundamental investigations in theoretical geomechanics.

Much of Jeffreys' well-known book "The Earth" (1924, 1929) is based on his own work, and this is especially true of the section on near earthquakes. However, the book owes its unique position not only to these original contributions, but also to the skill and insight shown in the building up of a self-consistent picture of the earth from the very diverse and apparently contradictory materials available at the time when it was written. Its great influence has been due to the width of interest and the critical skill as well as to the depth of learning of its author.

During the thirties Jeffreys' main interest was in seismology. In a series of papers he has discussed the available observations in detail and reduced the errors in the seismological time-tables by a factor of 10 or more. This work has had an important effect on our knowledge of the earth's interior and has yielded numerical information of surprising accuracy, and, for example, the radius of the earth's central core, is now known with an accuracy of a few kilometres.

Some of his early papers and the book "Scientific Inference" show an interest in the philosophical basis of the scientific method and in the theory of errors. This was intensified by the difficulties he met in adequately treating the seismological travel times, to which orthodox 'least square' methods are inapplicable. The discussion of these observations led to a series of papers on significance tests, and, finally, to a book, "The Theory of Probability", in which he discusses *de novo* the whole problem of the relation between observation and 'physical quantities'. The departures from orthodoxy have not proved universally acceptable, but it is generally agreed that Jeffreys has made an important contribution to a subject on which the last word has not yet been said.

Other topics to which Jeffreys has made material contributions are pure mathematics, the origin of the moon, the constitution of the planets, hydro- and aerodynamics. In particular, he gave the first mathematical discussion of the theory of aerofoils of finite thickness.

Other less relevant examples of the catholic interests of the Plumian professor of astronomy and natural philosophy could be cited. Whether as a specialized applied mathematician or as a teacher and leader of research, the eminent services he has rendered are most widely recognized.

A ROYAL MEDAL is awarded to Prof. James Gray for his distinguished work on the mechanism of posture and locomotion in vertebrate and other animals.

In 1933 Gray, by the use of cinematography, analysed the forces involved in the progression and turning of fish with long and short bodies. The inquiry reached its full development during the last ten years with the extension of these studies to vertebrates generally. In 1936 he discussed the swimming of dolphins; raising, the hydrodynamical problem of the type of water-flow past an undulating body. Later he analysed the locomotion of Amphibia and of snakes. The results of this part of the work led to a discussion of the mechanics of the tetrapod skeleton which was fundamental and placed an important part of the comparative anatomy of vertebrate animals on a functional basis for the first time. His work shows that the whole body of a tetrapod must be considered as a single functional unit; changes in the tension of one muscle being accompanied by a demonstrable pattern of changes in other muscles. Gray analysed and described the mechanical problems solved by tetrapods standing and moving over ground of varying slope and smoothness; he has also analysed the neuro-muscular phenomena responsible for the evident co-ordination of action. He showed the importance of peripheral reflexes in the initiation and maintenance of swimming movements in fish. This led him to the problem of the origin of locomotory patterns. His experiments on the neuromuscular system of annelids showed the major importance of patterns of peripheral stimuli.

This work, summarized in a Croonian Lecture, was later greatly extended by demonstration of the importance of peripheral reflexes in the locomotor activities of toads. It was found that there was no, positive evidence for the existence of central rhythm in these animals, while, on the other hand, the proprioceptive reflexes arising from the muscles provide an adequate basis for locomotor action.

Gray's work is responsible for an important change in the direction of research in the comparative anatomy of vertebrates. Before its appearance, skeletal structure was examined in extraordinary detail and yet little or no attention was paid to musculature and to the relation of structure to the whole system in action. More than any other, Gray has shown that comparative anatomy is certainly not a dead science.

Davy Medal

The DAVY MEDAL is awarded to Prof. Edmund Langley Hirst for his distinguished contributions to the chemistry of carbohydrates.

The first demonstration of the six-membered ring structure of an aldose derivative was offered by Hirst and Purves in their study of methylxyloside, which was published in 1923. Since then, in collaboration with Sir Norman Haworth over a number of years, and independently, Hirst has played a great part in the establishment of fundamentals in the field of carbohydrate structure. His prolific experimentation is characterized by the highest accuracy and has afforded conclusive answers to many questions of importance.

Of his joint work in the Birmingham School the following must be cited: the recognition of pyranose and furanose forms of the simple sugars, the isolation of a crystalline furanoside for the first time, and the determination of the constitution of sucrose and other disaccharides.

His independent work on optical rotatory dispersion in the carbohydrate derivatives introduced new methods of attack on constitutional problems, which were of immense service in his later work on the constitution of vitamin C. In that investigation of outstanding merit he determined the structure of ascorbic acid and studied a large number of related products. In 1933 he shared in the synthesis of ascorbic acid and in the study of the physiological activity of the synthetic vitamin.

His researches on the polysaccharides have been conspicuously successful over a wide field, and largely because of his development of new methods of end-group assay in the determination of structure. He has applied these methods successfully to starch, glycogen, and other polysaccharides, and to him we owe many advances in our knowledge of the nature of alginic acid, the plant gums and pectic substances.

The regularities and irregularities that have been disclosed have been of equal interest and unexpectedness.

Hirst has been a pioneer in unravelling the complexities of carbohydrate architecture, and to him must be attributed much of our present knowledge of this group of such great biological significance.

Darwin Medal

The DARWIN MEDAL is awarded to Prof. Ronald Aylmer Fisher for his distinguished contributions to the study of biological evolution.

A general principle that is consistently developed in Prof. Fisher's writings is that the course of evolution is not controlled by mutation but by selection operating upon the heritable variability which Mendelian recombination supplies.

In 1928 he was the first to suggest that dominance is the product of selection operating in the gene-complex of the organism. This theory he tested and confirmed experimentally with domestic poultry and later with mice.

The implications of his concept extend beyond the dominance phenomena, and underlie the whole theory of the modification of genic effects through selection acting on the gene-complex. This enables a character, even when under unifactorial control, to be adjusted to the needs of the organism. To Darwin, selection was a mechanism for rejecting the bad and conserving the good; it is largely to Fisher that we owe the view that it may mitigate the bad and enhance the good effects of the hereditary units.

The studies of Fisher on abundance and variability, the first of them undertaken in collaboration, have provided means for proving in general terms the proposition, implicit in the modern concept of evolution, that genes having minute favourable effects are in process of being spread through populations and are bringing about evolutionary change at the present time.

Fisher's methods of population analysis, developed from 1930 onwards, have made it possible to study the numerical aspect of animal communities with an exactitude previously unattainable.

The special opportunities for evolutionary study presented by polymorphism have always attracted Fisher, and he has repeatedly analysed the balance of selective agencies which may be involved. This point of view is apparent in his extensive work on human serology. He has also studied a polymorphism which had especially interested Darwin, that of the heterostyled plants, and he has extended the subject to elaborate the general theory of crossing-over in polyploids—a pioneer work of wide application.

Fisher's great contributions to statistics and to experimental design have provided tools now deemed essential to the quantitative biologist. But they are fundamental also to the experimental studies of evolution which have become so important a feature of modern biological research.

Hughes Medal

The HUGHES MEDAL is awarded to Sir Robert Watson-Watt for his pioneer researches in radio-telegraphy.

Watson-Watt has been a leader in the field of radio research since the early nineteen twenties. He began to work on the subject of atmospherics in 1915, paying attention at first to the subject of the direction of arrival. He published the first English studies on this subject, establishing the 'cum-solar' swing of the place of origin throughout the day. He developed the cathode-ray direction-finder as a means for finding the direction of arrival of individual atmospherics. This has proved of immense value in the location of thunderstorms during the War. With a number of collaborators he later studied the wave-form of atmospherics.

He has been the leading exponent of the use of the cathode-ray oscillograph for a great variety of purposes in physical research.

Watson-Watt was the leader of the earliest British work on radar, or radiolocation, as it was then called. Although the basic principles were known, enormous technical difficulties had to be overcome before radar could be developed in the form of an operational instrument. That these difficulties were, in fact, overcome was due, in Great Britain, more to Sir Robert Watson-Watt than to any other man. He is now turning with equal insistence to the peace-time applications of radar, especially in the service of civil aviation.

New Officers

Sir Alfred Egerton now lays down his office as Physical Secretary of the Society. During the past ten years he has shown a deep concern for the Society's welfare, and the utmost willingness to undertake onerous duties.

I would like to remind you of some of his many activities. In the early days of 1939 he was chiefly instrumental in the creation of a Central Register of Scientists. The significance of this action by the Society was by no means exhausted by the end of hostilities. Almost in the first month of the War he took a leading part in persuading the War Cabinet to set up a Scientific Advisory Committee. These efforts, after initial setbacks, succeeded in October 1940, and the Committee functioned usefully during the war period and was the forerunner of the present Advisory Committee on Scientific Policy. I cannot deal at length with his services in a more personal capacity, for example, to the Ministry of Fuel and Power, but we recall with gratitude his interest in the re-organisation of the Gassiot Committee and in the survey, which the Society conducted, of the needs of fundamental science after the War. He has been an ever-welcome guest overseas, and has a distinguished record as an ambassador of science. His great services to the Empire Scientific Conference of 1946 and its offspring, the Scientific Information Conference of the present year, are fresh in our memory. He worked zealously, carefully and effectively—an unusual and difficult combination—and the results will benefit every part of the Commonwealth in which scientific activity exists.

Sir Alfred will continue to act as virtual representative of the Society in several important capacities; if I may mention just one as an example, it may be as a member of the Scientific Advisory Council for the Festival of Britain, 1951.

We shall not be able to take so much advantage of his habitual generosity as in the past, but, in case of need, we shall certainly seek his help and advice.

Prof. David Brunt has been elected as the Physical Secretary of the Society. To him we offer the most cordial welcome and good wishes, coupled with thanks for his willingness to assume the duties and responsibilities of the office.

One of the most valuable of the traditions of the Society is our claim to exercise initiative when the circumstances suggest a new departure. So far as I am aware it has not previously been thought desirable to designate any person as honorary librarian to the Society; but the Council felt that the present chairman of the Library Committee had given services which were probably without precedent. Prof. E. N. da C. Andrade's knowledge of the older scientific literature is unrivalled, and has been freely available to the great advantage of the Society.

The retirement of Mr. H. W. Robinson as librarian occurred at the end of March of this year. He joined the staff in 1902 and assisted the chief clerk and the librarian; in 1910 he became library assistant and in 1930 assistant librarian. He has been librarian since 1935. His work for the Society and its Library has been invaluable, and we may recall with special gratitude the care he showed in the safe bestowal of our treasures in the time of danger. An earnest student of the history of science, he has paid special attention to the study of Robert Hooke, on whose life and work he is a recognized authority. In expressing our gratitude for his devoted labours, we note with pleasure that Mr. Robinson will continue to assist Prof. Turnbull in editing the Newton letters.

Scientific Information

The outstanding event of the past year in connexion with the Society has been the Scientific Information Conference. We welcomed delegates from the countries of the Commonwealth and also from the National Academy of Sciences of the United States, and from Unesco. It can thus be claimed that the whole of the English-speaking scientific world was well represented. More than half of all scientific literature is written in English, and in making such a comprehensive review of scientific information services, I think the Society may be judged to have taken a timely initiative. We were gratified by the interest shown by Fellows and the time and energy so freely given by them to ensure the success of the Conference.

The Council of the Royal Society received from the Conference many recommendations dealing with the publication of papers reporting original work, abstracting services, reviews and annual reports, library services, classification and indexing, and other relevant matters. It has been decided to implement these, so far as proves possible, with the aid of a Treasury grant, and for this purpose the Council has set up an Information Services Committee, which has just held its first meeting. I believe that an energetic follow-up of the recommendations will result in real progress. The value of the Conference itself, irrespective of these recommendations, should not be under-estimated. Divergent points of view were advocated, and many of the difficulties besetting the free and rapid communication of new knowledge were at least recognized as the result of discussion and, in many cases, were removed. The problem is a complex one, and its solution demands both due regard for traditional methods and an acute appreciation of novel techniques.

Having given this lead, the Society will now be expected to play an increasingly important part, nationally and internationally, in improving scientific information services.

It is doubtful whether the general progress of science has ever been more impressive than at the present time, and this fact emphasizes the importance of adequate outlets for the publication of the great volume of original work that is being poured out. Formidable archives are undoubtedly accumulating. To meet the demand many new journals have been founded, and here is a short list of them. *Agricultural Chemicals*, Baltimore, 1946; *British Journal of Pharmacology and Chemotherapy*, U.K., 1946; *Hungarica Acta Chimica*, Budapest, 1946; *Journal of Colloid Science*, N.Y., 1946; *Journal of Polymer Science*, N.Y., started publishing 1946; *Zeitschrift für Naturforschung*, Wiesbaden, 1946; *Acta Chemica Scandinavica*, 1947, Chemical Societies of Denmark, Finland, Norway and Sweden; *Analytica Chemica Acta*, N.Y., 1947; *Biochemica et Biophysica Acta*, N.Y.; *Die Makromolekulare Chemie*, Basle, 1947; *Food Technology*, N.Y., 1947; *Heredity*, London, 1947; *Journal of Glaciology*, U.K., 1947; *Nucleonics*, N.Y., 1947; *Acta Crystallographica*, U.K., 1948; *Acta Physica Austriaca*, Vienna, 1948; *Annali di Geofisica*, Rome, 1948; *Australian Journal of Scientific Research*, Australia, 1948; *Deutsche Hydrographische Zeitschrift*, Hamburg, 1948. Furthermore, the scientific reviews are constantly being extended in scope; one can even be thankful that they show a tendency to overlap. *Nature*, playing a more important part than ever before, is now supplemented by *Research*, while *Endeavour*, *Science Progress* and *Discovery* worthily maintain our reputation in the field of popular exposition. The Press is far better informed on scientific affairs than was the case a few years ago, and we can anticipate useful autocatalysis in the reaction between public appreciation and public information.

A Science Centre

A year ago I mentioned the formation of a committee to study the means whereby adequate accommodation for the scientific societies may be made available, and tactful reference to its activities will be found in the Report of Council. Without being too indiscreet, it is possible to provide some further information on a subject of great interest to the Fellows of the Society. In the first place, the Scientific Accommodation Committee has so far considered only the long-term problem, and it is matter for congratulation that representatives of so many interested parties reached full agreement on this aspect. It was unanimously agreed that the institution of a science centre would provide the best solution. Naturally, everybody would like to know where that will be and exactly what the proposal involves. In regard to the first point, a specific suggestion is being explored, and we hope that it will soon be possible to announce a definite outcome, such that a suitable site will be allocated for the eventual creation of a worthy science centre. It is unlikely that this site will please everybody; but we have reason to believe that a large majority will welcome it in view of the many advantages secured. In any event, we have the assurance that favourable consideration will be given by Ministers to transference to a better site, should such be found.

The course of the discussion showed that the co-operation of several scientific societies depended on that of the Royal Society, and your representatives accepted the flattering implications, though not without some hesitation. To speak directly, that means willingness, if necessary in the general interest, to leave Burlington House and to function as the heart of the science centre located elsewhere.

The elaboration of so far-reaching a scheme is not at all a simple matter, and involves polypartite negotiations and agreements. The Fellows of the Society will be directly consulted on the major issue just so soon as it can be put to them in a precise form.

One possibly related matter may be adumbrated at this early stage, so that we may think about it.

The Report of Council mentions the reconstitution of a 'Rutherford Memorial Committee', which has various schemes under consideration. At the last meeting of this Committee I ventured to suggest that, as one aspect of the memorial, a 'Rutherford Hall' of noble design should form a part of the science centre, and this was given general approval by the Committee and later by Council.

Freedom of Science

Unfortunately, I must now turn from these roseate dreams of future glory to an incident of the present which has rudely disturbed our peace of mind. It is possible that our information is incomplete, or even inaccurate; but it is probable that we have ascertained the more important facts of the case.

I refer to the report that eminent Russian biologists have been constrained to subscribe to interpretations of the data in the field of genetics which they had previously rejected, or perhaps had thought unworthy of serious consideration. According to *Pravda*, "The Academy of Sciences forgot that the most important Principle in Science is the Party Principle". That is a forthright declaration which leaves little scope for ambiguity. The incident is evidently of political, rather than of scientific, importance, and the Royal Society is not concerned with politics.

We regret that the Academy of Sciences of Moscow has broken off its long correspondence with us. We trust that the new conditions will not seriously impede the advance of biological science, for which such qualifications as 'Western' are as irrelevant as they would be for a multiplication table. We impute no blame and express no opinion as a body, but that does not mean that we must take no cognizance of the occurrence, which may have some lessons for us, at least by way of analogy. For example, we may observe that governments are not infallible, yet must be obeyed. This reflexion should make us more than ever alert to preserve intact the prized freedom of science in our own domain. Actually no direct attack is likely here, and should the unexpected happen it will certainly not be along the lines of compelling us to espouse some particular scientific theory or doctrine. Conceivably it could take the more subtle form of control of the character and direction of our scientific work. There is immediate danger in the current deprecation of fundamental research, not of course absolutely, but relatively, in comparison with technological applications. I hope it will be the opinion of all Fellows that the Royal Society should take a leading part in upholding our ideals and in clarifying ideas on these topics, and particularly in insisting on the vital role which the highest kind of disinterested investigation must take in the life of the community. It is certainly not sufficiently realized that the body scientific can only flourish when all its organs are in a healthy condition. As in a biological equilibrium, there is a natural interdependence between pure and applied research. Pure science is fertilized by the advance of technology and *vice versa*. It would be quite consistent, though lamentable, to take up the position that we will have no more research at all, and devote our energies to the exploitation of present knowledge. But it is impossible to dissect the elements of real progress. If we isolate one of the limbs of the organism it will not grow, and will soon die.

Progress of Science

I do not propose to add more than brief comment on new scientific discovery. It will be conceded that the great privilege of addressing the Fellows of the Royal Society is not without its own peculiar embarrassments. For example, I have recently delivered two lectures summarizing results of many years in my own field of work. If I venture on other ground I shall be speaking as an amateur to some of the leading specialists in the world.

Without attempting any kind of assessment of values, or any completeness of survey, I will mention a few things that have been brought to my notice in recent months, often as the result of casual conversation.

Two years ago I referred to the very great value of spectroscopic methods for the study of complex molecules of organic compounds. Since that time there have been striking applications of both ultra-violet and infra-red absorption measurements which have solved some otherwise intractable problems. But one difficulty that threatened to impede progress was the management of minute quantities of material, especially in the solid state.

Dr. C. R. Burch, Warren Research Fellow, has built a reflecting microscope which is perfectly achromatic, and this has now been harnessed to an ultra-violet spectrometer by Barer, Holiday and Jope, and to an infra-red spectrometer by Thompson, Barer and Cole. In the latter case the spectral range 1–14 μ can be covered, and the results are identical with those obtained with larger specimens in more usual apparatus.

The spectra of single biological cells or single crystals weighing less than 10^{-7} gm. have been measured. Polarized infra-red radiation has also been used, and this promises to open up a new method for study of biological specimens, such as muscle fibre, in which orientation exists, as well as new possibilities for crystal analysis. This arises from the relations existing between absorption and orientation of the vibrating groups, whence the angle between certain characteristic bonds and the crystal axis can be determined. Measurements have already been made with minute quantities of new antibiotics and similar substances in connexion with their identification, or the diagnosis of their molecular groups.

The importance of this advance for organic chemists and biochemists cannot be exaggerated. It will surely lead to the routine study of the infra-red absorption of many new compounds, and the relation between the spectra and constitution will therefore become still better known. As the method thus increases in power the demand for its help must also become more insistent.

I am most grateful to Dr. H. W. Thompson for advance news of this remarkable development in technique, details of which will be published in a short time. Soon we shall all be repeating the wistful inquiry that ends Barrie's play: "How much do they cost—those machines?"

I cannot pretend to be competent to discuss applied mathematics, astronomy, or physics; but it is obvious even to the uninitiated that great advances are being made in our knowledge of the mesons and of nuclear fission.

Sir George Thomson, in his Bakerian Lecture, gave a fascinating account of the evidence provided by study of the effects of cosmic rays on atoms, while Prof. E. O. Lawrence, with the aid of his new synchrocyclotron, has been able to produce mesons in the laboratory for the first time.

Prof. E. A. Milne's forthcoming new book will evoke lively discussion, for he tells me that acceptance of his theoretical system involves the assumption that Planck's constant h varies secularly with the time.

On the technical side we hear from America of a new type of valve, a crystal of germanium, which can be made to function as an amplifier.

Coming nearer to my personal interests, the chemists and biologists of Parke, Davis and Co. are to be warmly congratulated on their discovery and investigation of chloromycetin, a new antibiotic which has proved to be highly effective against scrub-typhus and certain analogous infections. The constitution of chloromycetin has not yet been disclosed; but it is said to be known, and apparently the substance has been synthesized. It makes possible the first satisfactory chemotherapy of a disease caused by a Rickettsia, and opens up the possibility of the control of virus diseases more generally.

Another discovery of vast medical, agricultural and biochemical interest arises from the isolation of the intrinsic anti-pernicious anæmia factor from liver. This brilliant consummation, a further triumph of modern chromatography, has been reached by A. Lester-Smith and his colleagues in the Glaxo Laboratories and by a team of chemists of Merck and Co. (New Jersey), led by K. Folkers. The red crystalline substance contains cobalt in a co-ordination complex which has a molecular weight of about 1,600 and probably includes three atoms of phosphorus. It is proposed to call the factor vitamin B_{12} and it is one of the most physiologically active of known substances, a dose of one microgram daily being fully effective therapeutically.

The picture is very quickly being filled in; we heard from Dr. Marston quite recently of his outstanding researches on the cobalt requirements of sheep. A defect of cobalt in the soil leads to sickness and stunted growth with anæmia. Other recent and related work by Drs. Tosic and Mitchell at Aberdeen concerns the assimilation of cobalt by micro-organisms. We may be sure that knowledge of the constitution of B_{12} will suggest other correlations, perhaps with nucleotides, perhaps with folic acid, which will be of vast significance. The molecule is not especially complex by modern standards and its structure can be determined, provided sufficient effort is made. If I am reminded that we are unable to synthesize penicillin, the reply would be that the problems are not comparable. Analysis of substances of this degree of complexity must nowadays always succeed, whereas synthesis may present a difficulty of a different order altogether. The trouble will be to get enough of the factor for investigation by ordinary methods, and this is a good illustration of the value of micro-physical devices. I am told that the infra-red absorption spectrum, determined by the new technique previously mentioned, has already given valuable information, confirming the presence of PO, NH and OH groups, and indicating absence of aliphatic CH, but probable presence of aromatic CH as in benzene or purines.

We seem to be on the verge of great discoveries in another field perhaps not entirely unconnected with the last-mentioned, namely, the problems connected with the effects of chemical substances on cell growth, including malignancy. There cannot be said to be any satisfactory treatment of cancer by chemical means, though various agents exert a beneficial effect in special cases. Such are stilbœstrol, testosterone and the so-called nitrogen mustards. Of these, stilbœstrol has the best claim to be regarded as a curative agent in a proportion of cases, and the halo-alkylamines ameliorate the condition of the patient. In the United States, Dr. Rhoads and his colleagues have paid much attention to antagonists of folic acid. These are synthetic compounds the molecules of which are planned to resemble those of folic acid. Several of them have been found to exert an inhibitory effect on the bone marrow, producing anæmia, which can be reversed by folic acid. Similar antagonism is observed with bacteria, and furthermore Hertz has reported that certain of these substances inhibit the action of stilbœstrol on the oviduct of the chick.

One of the most promising of the substances is called A-methopterin. This is folic acid with an amino-group replacing hydroxyl and a methyl group replacing hydrogen, quite a close analogue. The substance is anti-folic, anti-œstrogenic, and it has a definite inhibitory effect on the growth of tumours in laboratory animals, as well as of malignant cells in tissue culture. Folic acid is regarded as necessary for the growth of all cells, and the hope is to find a substance of low toxicity which will antagonize this factor to the level necessary to immobilize the more sensitive malignant growth without serious detriment to normal cells. It is known that laboratory work has encouraged clinical trials, but the results have not yet been disclosed.

Dr. T. B. Heaton and my wife have published a preliminary account of work which finds its origin in observations made many years ago on a growth-inhibiting constituent of yeast (Heaton, 1926). This was a differential growth-inhibitor affecting the connective tissue cells but not the epithelia of cultures *in vitro*.

They have now prepared carbohydrate material from wheat middlings which is either itself active, or more probably contains an active principle. This produces retrogression of the implanted Walker carcinoma in rats.

It is decidedly interesting to find such a substance in a foodstuff; it may even be a vitamin. Since in some of the earlier experiments the material had been held at a low pH, the formation of hydroxymethylfurfuraldehyde was a possibility, and it was known that many aldehydes possessed growth-inhibitory properties. It was found that hydroxymethylfurfuraldehyde, or better its polymeride, also caused the retrogression of the tumours. The connexion, if any, between these findings is not yet clear.

At the Chester Beatty Research Institute, Dr. A. Haddow and his colleagues have tested the effects on normal growth of a number of pyrimidine derivatives. The developments have sprung from experiments designed for other purposes—and the sequence is of more than passing interest. It started with the yellow enzyme and a series of experiments designed to test the effect on growth of a series of synthetic analogues of the flavins.

Administration of 9-phenyl-5 : 6-benzo-*iso*-alloxazine to albino rats was accidentally, and most unexpectedly, found to produce an orange-yellow pigmentation of the hair (Haddow, Elson, Roe, Rudall and Timmis, 1945). Pursuing this curious observation, other coloured substances of a similar type were tested, and among them xanthopterin, the butterfly wing pigment, first isolated by Wieland and Schöpf in 1925. This did not colour the coat but produced a significant enlargement in the size of the rat kidney. It was an actual growth of the organ due to a great outburst of cell division in the kidney tubules.

In the course of still another research, that on the carcinogenicity of many styrylpyrimidines (Haddow and Kon), it was found that two substances of this group closely allied to xanthopterin in structure had the same effect in increasing the growth of the kidney. This cannot be mere coincidence and proves that the effect is a primary one of xanthopterin and the related pyrimidines on the cell. The phenomenon has been observed in the rat, mouse, *Peromyscus*, the rabbit, hamster and guinea pig.

Now xanthopterin is of natural occurrence in the kidney and it is possible that it is present as a growth regulator. Its structural relationship with folic acid will not be overlooked. Haddow and his associates feel that it is at least as important to study the means by which normal growth is so delicately adjusted as to inquire directly why the malignant cell is unregulated.

There are further experimental foundations for these ideas which lead Haddow and his collaborators to surmise that the co-ordinated growth of the normal tissues may depend upon the supply of essential substances from an external source and that, contrariwise, malignant cells may have acquired the power to synthesize these essential substances, or their equivalents, themselves. Such suggestions are fully consonant with all that we know of the subject as a whole and give a new prospect for the chemistry of growth and differentiation.

I am much obliged to Dr. Haddow for kindly acquainting me with results and ideas which are not yet published in full and for permission to mention them to-day.

I would not like to leave this subject without an incidental reference to Berenblum's significant discovery of sensitization of tissues to the action of carcinogenic agents. The constituents of croton oil, for example, directly or indirectly, prepare the ground for a carcinogenic hydrocarbon in a remarkable manner. The underlying biochemical processes may be hard to bring to light; but the effort to do so would doubtless be repaid with interest.

As a drama like that of the pyrimidine group unfolds we can look back on the steps of the pioneers and be thankful that they selected the paths which led into such rich territory. But it often appeared to contemporaries that they were wandering into a barren wilderness. 'Whatever makes Hopkins think that there can be any possible interest in the pigments of butterflies? Why does Windaus waste his time and talent on that impossible substance cholesterol? I have heard those actual questions asked in past years and would invite consideration of the answers that can be given to them now.

Another thought arising from recent progress is that the world of biochemistry, though of vast extent and interest, is finite, and we are beginning to sense the existence of its boundaries. We seem to encounter the same thing more often than might be expected; coincidences are indeed of frequent occurrence.

An example has already been mentioned and another is the recent discovery that the photodynamic colouring matter of St. John's wort, hypericin (Brockmann *et al.*, 1939, 1942; Pace and McKinney, 1941; Dhéré, 1939, 1943), is closely allied to a pigment of the Aphididæ, erythroaphin, studied by A. R. Todd and his collaborators at Cambridge (1948). Further, these substances are related to a mould pigment, oxypenicilliopsin, isolated by Oxford and Raistrick (1940). The pigments are *bis*-anthracene derivatives of some kind and it is surprising to find these little investigated and highly characteristic substances so widely distributed in Nature.

A notable coincidence in my own field of work arose very recently from a theory of Woodward regarding the course of the synthesis of strychnine in the plant. He advanced what seemed at first the fantastic idea that a benzene nucleus, originally that of dihydroxyphenylalanine (or tyrosine), suffers fission so as to give two oxidized chains which enter into further transformations.

Transferring this mechanism piecemeal into an entirely different group of alkaloids, it was found to predict that constitution of emetine which can now be experimentally demonstrated to be correct. I am glad of this opportunity to say that I was unaware until quite recently of parallel, independent work by Dr. H. T. Openshaw on the constitution of emetine. This was submitted for publication some months ago and includes the establishment of one detail of the structure not fully proved by the work of Späth, of Pailer and of Karrer. A few months ago no connexion whatever could be discerned between strychnine and emetine, they seemed poles apart. Now at one stroke they are connected by recognition of a common and remarkable type of biogenesis.

A PROPOSED INSTITUTE OF BIOLOGY

By DR. J. F. DANIELLI

INSTITUTES or analogous foundations have rendered great services to physicists, medical men, engineers, chemists, anthropologists and many other professional groups. No such foundation exists to serve the needs of biologists. Recently the Biological Council, consisting of representatives of nineteen different biological societies, was asked by a number of these societies to examine the possibility of forming an Institute of Biology. In a preliminary investigation the views of a number of representative biologists were obtained, and information was also available from the Institute of Biology recently established in the United States under the auspices of the National Research Council.

There are two aspects of an Institute which are of general interest: on one hand there is the daily life of an Institute; and on the other hand, there is the long-term influence of an Institute on policy.

The setting up of an Institute would immediately give to biologists a central address and general office service, and should ultimately provide a club and meeting rooms. An Institute would produce a bulletin to carry news and notices, maintain a watch on legislation and international matters of interest to biologists, maintain an employment bureau, and protect the standards of employment of its members, if need be by providing legal aid. A public relations service would be maintained, members would be advised in their dealings with the Press and with publishing firms. Special income-tax problems would be considered and the establishment of special relationships with trading firms and with insurance offices would be sought. Such day-to-day activities constitute a group of sound reasons for forming an Institute.

Of equal importance are the arguments based on consideration of policy. These include:

(*a*) The lack of a representative body of biologists. This causes two difficulties. It is difficult for those who are not biologists to obtain a measure of the balance of biological opinion on matters which may, for example, come within their province of administration. It is also difficult for biologists to place proposals before Government and other bodies, since at present such proposals cannot receive the backing of a representative body.

(*b*) Biology is becoming of increasing importance in industry and for the economic and physical well-being of the country. But at present the authority of biologists in these fields is restricted, and often in consequence insufficiently serious consideration is given to the purely biological aspects of a problem. The modification of this position is hampered by lack of professional organisation, by the general ignorance of biological factors and by the prevailing dominance of the strong professional organisations of chemists, physicists, veterinarians and medical men.

(*c*) Many biologists are now going into industry and their numbers are likely to increase. In the absence of any recognized Institute of Biology there is a tendency for membership of academic societies to be quoted as a qualification. This is an undesirable practice which may reach serious proportions. It did so, for example, in the cases of the Chemical Society and the Psychological Society. The formation of a recognized Institute with established qualifications for admission would put an end to this practice.

(*d*) Biologists are still badly paid in comparison with other professional groups. It is felt that this is at least in part the result of there being no professional body to look after the interests of biologists.

(*e*) The channels whereby biologists may be recruited are sometimes inadequate, and appointments too often depend mainly on chance. This situation would be improved by formation of an Institute with an appointments register. It is of interest that, in one recent year, out of the ten thousand members of the Institute of Chemistry, no fewer than one thousand made use of the appointments register.

(*f*) The formation of an Institute of Biology, embracing both academic and applied biologists, would be of national service, since it could assist in securing better financial support for biological research. It would also perform a most valuable service in surveying the position of biological science in general education, and the more specialized training of professional biologists.

With these considerations in mind, the Biological Council has decided to conduct a postal ballot of biologists, the distribution of ballot papers being made by the affiliated societies. In this ballot biologists are asked to state whether they would support an Institute, and to give the Council their opinions on the formation of an Institute.

An Institute can be formed only if a sufficiently large number of biologists are prepared to support it. If this support is forthcoming, the Biological Council will call a central meeting of biologists, at which officers and a provisional council can be elected. For the first year of its foundation the Institute could be run on a largely voluntary basis, during which time a constitution would be evolved, office premises found, etc.

The Biological Council envisages the Institute being open to all who are engaged in biology as a profession. Those joining would probably fall into two categories of membership, namely, associate members, holding an honours degree in biology or its equivalent, and full members, holding a degree of D.Sc. or its equivalent. In addition, provision should be made for scientific societies to become affiliated to the Institute. The Council of the Institute we envisage as elected in two ways—some of the members being elected by the individual members of the Institute, and others nominated as representatives of the affiliated societies. But the final decision on these details would, of course, be taken when a constitution is agreed upon.

It is not intended to exclude people who have no degrees, or to limit full membership to those with D.Sc. degrees. There is no reason why a biologist should not be either an associate or full member while having no degree, provided he has a training, or has achieved a status, which can be regarded as equivalent to that indicated by a degree. However, it may well be that the foundation members will prefer to have only one category of membership. All decisions on such matters, including the constitution, will, of course, rest with those biologists who indicate, by voting in the Biological Council's ballot, a desire to participate in the formation of an Institute of Biology.

Biologists who are members of a society affiliated to the Biological Council will receive a ballot paper from their society. Those who are not members of an affiliated society may obtain a ballot paper from one of the joint secretaries of the Biological Council, namely, Dr. J. F. Danielli, The Chester Beatty Research Institute, Royal Cancer Hospital, Fulham Road, London, S.W.3, or Dr. W. P. K. Findlay, Forest Products Research Laboratory, Princes Risborough, Bucks, or Prof. J. Z. Young, Department of Anatomy, University College, Gower Street, London, W.C.1.

The societies affiliated to the Biological Council are: Anatomical Society, Genetical Society, British Mycological Society, Linnean Society, Nutrition Society, Society for General Microbiology, Pathological Society, Biochemical Society, Pharmacological Society, Physiological Society, Society for Experimental Biology, British Ecological Society, Royal Entomological Society, Marine Biological Association, Association of Applied Biologists, Royal Horticultural Society, Eugenics Society, Association for the Study of Systematics in Relation to General Biology, and Society of Applied Bacteriology.

OBITUARIES

Prof. E. F. Burton, O.B.E.

Eli Franklin Burton, director of the Physics Laboratory, University of Toronto, died in Toronto on July 6, 1948.

Born in February 1879, he attended high school in Toronto and took the honours course in mathematics and physics at the University of Toronto, graduating in 1901. His first researches were carried on under the late Prof. J. C. McLennan and included work on the penetrating radiation from the earth (they just missed discovering the cosmic rays). Burton then proceeded to Cambridge in 1904 as an 1851 Exhibition Scholar and worked under J. J. Thomson on colloidal particles. Returning to Toronto, he assisted McLennan in the fitting up of the new physics building (now called the McLennan Laboratory) and obtained his doctorate of philosophy in 1910. He was promoted to an associate professorship in 1911 and to full professorship in 1924. In the First World War he was a member of a team consisting of McLennan, Satterly, Dawes and Patterson (of the Meteorological Service of Canada), and occupied himself with the problem of the estimation of helium gas in the natural gas of Canada and its extraction therefrom for use in balloons. He also was acting head of the department when McLennan was called to Britain to assist in the scientific work at the Admiralty.

On the return of peace and McLennan, Burton and his assistants continued his work on colloidal solutions and later published a monograph on the physical properties of colloidal solutions. A third edition of this book was published with the collaboration of Miss May Annetts in 1936. At one time he was very interested in the application of colloidal arsenic solutions to abate the onset of cancer, and in this work he was assisted by Dr. Hendricks. Although he fought hard for recognition of his method and he had concluded from X-ray photographs that the method had some advantages, the medical profession remained cold and the work was eventually dropped.

Just after the beginning of the Second World War, Burton had the intuition that radio-location would play a vital part in the contest. He tried hard to interest the Services and to get them to send their brighter men to take a course in radar; but they declined. Then he enlisted the support of a Toronto Kiwanis Club, who provided sufficient monetary assistance to enable the Physics Department of the University of Toronto to run a summer course in 1940 for about twenty selected men. Burton had the satisfaction in later years of knowing that some of these men, in ship and on land, filled very important posts in the Empire radar services. In the succeeding years he almost forced the Services to start classes in radar not only in Toronto but also across the Dominion, for the Royal Canadian Air Force and the Canadian Army, and eventually a large number of men were trained who served in all parts of the world.

Burton was also a director of Research Enterprises, Ltd., a Crown research company managed by Colonel Eric Phillips, now chairman of the board of governors of the University of Toronto. 'R.E.L.', as it was called, built huge factories and laboratories at Leaside just outside Toronto in which all kinds of apparatus for war purposes were made and assembled; mention need only be made of radar outfits, optical glass, periscopes and range-finders. Because the men could work under better and quieter conditions than in Toronto, the very complicated radar sets for the large battleships of the Navy were built at Leaside. As side issues, Burton promoted (with Pitt) the invention and design of proximity fuses for shells, and other investigations on the flight of shells, and directed research on problems in audition connected with shell shock. For this work he was awarded an O.B.E. in 1943. It was a great grief to Burton when, after the end of the War, the Government decided to relinquish all the work at 'R.E.L.' and to sell parts of the establishment; he had hoped that a portion of it would be maintained as a factory for the manufacture of scientific apparatus for use in Canada.

On McLennan's retirement from Toronto in 1932, Burton became director of the Physical Laboratory, and soon after that developed with A. Pitt and others the study of valve circuits, leading in one instance to the Burton–Pitt electrical method for the determination of the water content of grains and soils. The low-temperature work (initiated by McLennan) on helium and the superconductivity of metals was carried on by Burton and others. The study of the viscosity of liquid helium I and II, with the discovery of the very low viscosity of liquid helium II, opened up a new field which he, with the help of Wilhelm and Misener, vigorously prosecuted. Also, with the help of Grayson-Smith and others, he carried on the work of superconductivity and in 1934 published a small book on the subject.

Elected to the fellowship of the Royal Society of Canada in 1913, he became president of the Mathematics, Physics and Chemistry Section in 1934–35 and was awarded the J. M. Tory Medal in 1947. He was also president in 1931–32 of the Royal Canadian Institute, a Toronto society which gives public lectures on scientific subjects adapted for the general public. As a member of the National Research Council of Canada for many years, he gave much of his time and energy to the furtherance of scientific work in Canada and for providing means for young Canadians to stay at home and develop their own country rather than emigrate to the United States.

During the war years, Burton encouraged Prebus and Hillier to build an electron microscope. This was based on an existing European design and was probably the first electron microscope set up on the American side of the Atlantic. Burton gave Hillier and his successors all the backing he could, so that the Toronto School of Electron Microscopy has been in the forefront of this work, and many of the men who have been through it have secured important posts in the United States.

The physics building of the University of Toronto was sorely overtaxed for space during the war years, and as soon as labour was available Burton persuaded the board of governors to build a new wing to the building, which increased the total space by about thirty per cent. The new wing was named by the governors the "Burton Wing", and Burton was enabled to see it unofficially opened in May 1948. In this new wing there are special suites for research work on low-temperature problems, radio-work, and especially for electron microscopy. The Electron Microscope Society of America met here in September to honour the man who had done so much, but unfortunately he had passed away before he could receive their congratulations.

Dr. Burton was one of the most cheerful and kindly of men. Unfortunately, in later years his energy was undermined by diabetes and heart-shocks, and in his last year failing memory and eyesight robbed him of his lively good humour. He leaves an honoured name in Toronto and Canada generally. He is survived by his widow and one son and one daughter.

JOHN SATTERLY

Dr. Susan Isaacs, C.B.E.

SUSAN ISAACS died on October 12 at the age of sixty-three. Few can have had a greater influence in our time on the upbringing and education of children; indeed, the modern trend towards full recognition of the human aspect of nursery school and subsequent education owes much to her work.

Dr. Isaacs was the daughter of William Fairhurst, of Bolton, Lancashire, and of Miriam Sutherland. Educated at Bolton Secondary School and at the Universities of Manchester and Cambridge, she became a research student at Cambridge in the Psychological Laboratory in 1912, and then lecturer in psychology at Darlington Training College. In 1924 she was invited to become principal of the Malting House School at Cambridge. It was during the following three years that she gathered the comprehensive data of children's behaviour, thoughts and feelings which she presented brilliantly in her two books "Intellectual Growth in Young Children" (1930) and "Social Development in Young Children" (1933).

In 1933 she was made head of the new Department of Child Development of the University of London, at the Institute of Education. She held this post with outstanding success for ten years. In the course of that time a large number of experienced teachers and educationists were enriched by the wide and deep new knowledge which she was able to impart, and above all by her vivid sense of every child as a full, living personality, needing to be imaginatively realized and understood in his own right.

Dr. Isaacs turned to the new insight offered by Freudian psycho-analysis as soon as this work became generally known in England, and joined the British Psycho-Analytical Society in 1921. She was appointed a psychologist on the staff of the London Clinic of Psycho-Analysis in the year 1931. She remained on the staff of the Clinic until her death, and contributed signally in a great number of ways to the scientific work of the Society and to the practical work of the Institute. She was a valued member of the Training Committee and of the Council.

Dr. Isaacs was a clear writer as well as teacher and lecturer; her books and scientific papers are well known to students of psychology to-day. Her small handbook for mothers and teachers, "The Nursery Years", written in 1929, is known all over the world; it was awarded the Parents' Magazine Medal in the United States. "The Children We Teach" is another little book which is widely popular. One of the two books published just before her death is "Childhood and After", containing essays and clinical psychological studies which belong to the later period of her life [see review on p. 871]. A chapter in it called "Children in Institutions", originally a memorandum presented to the Home Office Care of Children Committee, known as the Curtis Committee, 1945, was probably the most important single document consulted by that Committee.

Dr. Isaacs' gifts were based on a combination of intellectual and emotional factors. Her passionate interest in the conditions, first, of young children's education, and, secondly, of their general upbringing in the home, arose out of her own experiences. Her mother's death when she was just six, terminating a fatal and incapacitating illness which started when Susan was barely four, led her to find in her first elementary school in a Lancashire town in the 1880's a refuge and solace from the tragedy at home, but also to become very quickly a rebel against its manifold constraints and inadequacies. This disappointed eagerness and keen sense of what 'school' might have been like, but in fact was not, remained in the background of her mind throughout her growth and did much to shape her later life-work.

It became clear to her at an early stage in her development that mere criticism and mere abandonment of existing methods could bring no constructive results. She quickly assimilated and adopted the most advanced educational ideas current at the time, and her immediate response to the new teaching of psycho-analysis showed that no conventional opposition or resistances could stand in the way of her unhesitating acceptance of anything that offered her wider horizons and deeper understanding. In the same way, at a later stage, when Melanie Klein's ideas were first put forward in Great Britain, she was among the earliest to sense the further sources of knowledge which were now opening up. She saw how these new ideas could be developed to the general benefit of every child's upbringing, and from that moment she pursued that knowledge, and applied it untiringly up to the very last.

Her outstanding intellectual characteristic was an extremely rapid and comprehensive grasp of the matter in view and an ability to classify and summarize it, to present it with remarkable clarity, and to discuss it from various angles. Her exceptional capacity for instantly translating her thoughts and impressions into verbal expression served as a powerful instrument for all her other gifts.

It was characteristic of Susan Isaacs that when she found that there was a great deal which she had not yet encompassed, especially in the work of Melanie Klein, she decided (although she was already a member of the British Psycho-Analytical Society) to start again as a trainee and to go through the whole course. Thus she developed further, undergoing a second long personal analysis, and greatly enriched her own work and the contribution which she was eventually able to make to general psycho-analytic research. In her last years she devoted herself almost entirely to actual analytic practice, and felt this to be the most satisfying of the various kinds of work she had done.

In her husband, Nathan Isaacs, she had a constant friend and supporter, and a constructive critic.

DR. FRANTIŠEK BĚHOUNEK, lecturer in radiology at the Charles University of Prague, died at the end of October at the age of fifty. He had been a pupil of Mme. Curie and had developed a method for measuring atmospheric radioactivity. In 1926 he accompanied General Nobile on his ill-fated polar expedition, and when the airship *Citta di Milano* came to grief they were rescued by the Russian ice-breaker *Krassin*. Běhounek, with Heyrovský, wrote the standard Czech text-book of radioactivity.

NEWS and VIEWS

Science in the U.S.S.R.

In his presidential address to the Royal Society, delivered on November 30 (see p. 872), Sir Robert Robinson refers to the restrictions which have been placed on biological teaching and research in the U.S.S.R. Also simultaneously, his predecessor in the presidential chair of the Royal Society, Sir Henry Dale, has resigned his honorary membership of the Academy of Sciences of the U.S.S.R., because, as he says in a letter to the president of that Academy, "I believe that I should do a dis-service even to my scientific colleagues in the U.S.S.R. if I were to retain an association in which I might appear to condone the actions by which your Academy, under whatever compulsion, is now responsible for such a terrible injury to the freedom and the integrity of Science". In his announcement of his resignation, Sir Henry recalls that his election took place while he was president of the Royal Society, and that it was widely welcomed among British scientific men "as the symbol of a community of purpose between the scientists of our two nations . . . in defending, as we believed, the freedom of Science, as of all man's proper activities, from the threat of an aggressive tyranny". He points out that in the same year, 1942, N. I. Vavilov was elected a foreign member of the Royal Society in recognition of his contribution, by research in the U.S.S.R., to advances in genetics. But Vavilov had fallen into disfavour, and even now the Royal Society does not know whether he was alive at the time of his election to foreign membership. "More recent events, of which full reports have come to hand, have made it clear what has happened. The late N. I. Vavilov had been replaced by T. D. Lysenko, the advocate of a doctrine of evolution which, in effect, denies all the progress made by research in that field since Lamarck's speculations appeared early in the nineteenth century. Though Darwin's work is still formally acknowledged in the U.S.S.R., his essential discovery is now to be rejected there. The whole great fabric of exact knowledge, still growing at the hands of those who have followed Mendel, Bateson and Morgan, is to be repudiated and denounced; and the last few, who were still contributing to it in the U.S.S.R., have now been deprived of position and opportunity. This is not the result of an honest and open conflict of scientific opinions; Lysenko's own claim and statements make it clear that his dogma has been established and enforced by the Central Committee of the Communist Party, as conforming to the political philosophy of Marx and Lenin. . . . It remains to be seen whether such compliance with dogma is to be exacted in other departments of Science. So far as we know only that of the genetics encouraged by Lenin is now prohibited as alien to his political philosophy."

Dr. H. J. Muller, the distinguished American geneticist, has also resigned his honorary membership of the Academy of Sciences of the U.S.S.R.

Royal Society: Officers for 1949

At the anniversary meeting of the Royal Society on November 30, the following were elected as officers and council for the ensuing year: *President*, Sir Robert Robinson; *Treasurer*, Sir Thomas Merton; *Secretaries*, Sir Edward Salisbury and Prof. D. Brunt; *Foreign Secretary*, Prof. E. D. Adrian; *Other Members of Council*, Prof. J. D. Bernal, Prof. G. R. Cameron, Sir James Chadwick, Prof. S. Chapman, Prof. H. Davenport, Sir Frank Engledow, Prof. W. E. Garner, Prof. A. C. Hardy, Dr. C. H. Kellaway, Prof. G. F. Marrian, Sir William Stanier, Dr. H. G. Thornton, Prof. C. E. Tilley, Dr. A. E. Trueman, Prof. S. Zuckerman.

British Association: Newcastle Meeting, 1949

Next year the British Association for the Advancement of Science will meet in Newcastle-upon-Tyne (August 31–September 7). The Council has completed appointments to the various offices in the Association; these include: *President*, Sir John Russell; *General Treasurer*, M. G. Bennett; *General Secretaries*, Dr. Edward Hindle and Sir Richard Southwell; *Presidents of Sections*, Sir Harold Spencer Jones (Physics and Mathematics); Sir Alfred Egerton (Chemistry); Prof. W. J. Pugh (Geology); Prof. A. C. Hardy (Zoology); Prof. L. Dudley Stamp (Geography); Sir Alexander Gray (Economics); Sir Arthur Fleming (Engineering); Mr. M. C. Burkitt (Anthropology and Archæology); Prof. R. A. Peters (Physiology); Prof. Godfrey H. Thomson (Psychology); Prof. Lily Newton (Botany); Sir Fred Clarke (Education); Prof. N. M. Comber (Agriculture). The chairman of the Local Executive Committee is Lord Eustace Percy. The Lord Mayor of Newcastle has issued an appeal for a local fund of £4,000, and more than two hundred local volunteers are already making preparations for what is expected to be one of the largest meetings in the history of the British Association.

Unesco: New Director General

At the Third General Conference of Unesco now being held in Beirut, M. Jaime Torres Bodet, Mexican Foreign Minister, has been elected director general in succession to Dr. Julian Huxley, who has held office since the inception of Unesco two years ago. M. Bodet, who is forty-six years of age, was head of the library department of the Mexican Ministry of Education during 1922–24. From 1924 until 1928, he was professor of French literature in the University of Mexico. In 1929 he entered the Foreign Service and successively held positions in Mexican legations in Spain, Holland and France. During 1936–37 he was director of the Diplomatic Department of the Ministry of Foreign Affairs and the following two years he spent as chargé d'affaires in Brussels. From 1940 until 1943 he was Under-Secretary for Foreign Affairs, after which he was appointed Minister of Education. In this capacity he conducted a campaign against illiteracy, founded circulating libraries, organised a system of rural education, and devoted his whole time to the orientation and administration of education in Mexico.

Bicentenary of Berthollet

Claude Louis Berthollet, the associate of Lavoisier and himself a distinguished chemist, was not a native of France but was born at Talloires, near Annecy, in Savoy, on December 9, 1748. He was educated at Chambéry and at Turin. After taking his doctor's degree at the latter place he became physician to Philip, Duke of Orleans, in which capacity he made a name for himself as a chemical discoverer. In 1781 he was made a member of the Academy of Sciences of Paris and afterwards became director of the Government dye works. His discovery of the composition of ammonia was made in 1785 and that of the bleaching power of chlorine in 1786. With Lavoisier, Fourcroy and Guyton de Morveau he compiled the "Methode de Nomenclature Chimique" in 1787. He was one of the first to become a convert to the views of Lavoisier. The Revolution, while it brought him into danger, also called forth his organising powers, and it was largely due to his efforts that the saltpetre supply of France was maintained at a critical time. With Monge and Clouet he did much to improve and extend the manufacture of steel. In the reorganisation of the Academy and the inauguration of the Institute in 1795 Berthollet took an active part. Napoleon appointed him and Monge as heads of a Commission to select from the spoils of Italy the choicest works of art, and Berthollet was one of the group of French men of science who accompanied him to Egypt. In 1803 he published his well-known "Essai de statique chimique". Four years later he founded the famous Société d'Arcueil, comprising as members Laplace, Biot, Gay Lussac, Thenard and one or two others. After the suicide in distressing circumstances of Berthollet's son, the Society was broken up and from that time Berthollet lived in retirement. He was a senator, a grand officer of the Legion of Honour, and under the empire was created a count. He died at Arcueil after a long and painful illness on November 6, 1822. His character was amiable, frank and sincere. Though he enjoyed a great reputation in his time, he was modest and unostentatious and his honesty and courage were sufficient to impress even Robespierre. His eulogy was pronounced before the Academy of Sciences by Cuvier.

Radioactive 'Tracers' for Germany

A CONTRACT for the supply of radioactive tracers to approved research institutes in the Bizone of Germany has recently been placed with the Atomic Energy Research Establishment, Harwell, by the Joint Export–Import Agency, following the decision of the Isotope Allocation Committee of the Ministry of Supply in January last that radioactive 'tracers' produced in the Harwell Gleep could be made available for research work in Germany. The decision of the Isotope Allocation Committee was communicated to the authority responsible for the control of research in the British Zone, who immediately informed the U.S. Research Control Group. Together they approached the board of the import agency, supported by their respective public health advisers: and with the minimum of delay the Board authorized the import of radioactive tracers from Harwell into the Bizone.

Research institutes in the Bizone thus gain access to a range of radioactive tracers, the indigenous production of which is denied to Germany under Control Council Law No. 25 for the Control of Research. Their allocation within the Bizone is the responsibility of a small German committee, competent to decide where proper use will be made of the small total supply of 'tracers' at present available from Harwell to Germany. In order to assist the Committee in its task, a team of experts from Harwell visited Germany during October and demonstrated the latest ancillary equipment. Thus everything possible has been done to ensure that the maximum use shall be made of the limited quantities of radioactive 'tracers' which can be spared by the Atomic Energy Research Establishment at Harwell for export to the Bizone.

Research Council of Alberta

THE twenty-eighth annual report of the Research Council of Alberta (King's Printer: Edmonton) summarizes the work of the Council for 1947. All investigations in progress in 1946 were continued and a new project involving a survey of road surface conditions existing at selected places on the main highways of the Province, both where there was evidence of deterioration of the pavement and where the road appeared to be standing up satisfactorily in service, was commenced. The Council has continued to take a close interest in the bituminous sand separation plant being erected at Bitumount on the Athabaska River, and further laboratory work has shown that the loss of oil in the hot separation process is not due to filming on to particle surfaces but to the flecks below a critical size being enmeshed among the particles and afterwards, on redispersion of the tailings, settling with the clay, increase of clay content in the bituminous sand decreasing the oil recovery. Work on the applicability of water-flooding to the bituminous sands has continued, as well as on the systematic examination of Alberta coals and on the carbonization of low-grade sub-bituminous coals in the pilot plant low-temperature retort designed on the principle of a vertical shaft carbonizer. Investigations on the preparation of Alberta coals for the market and on some aspects of the chemical constitution of coal have been commenced. The Gasoline and Oil Testing Laboratory has widened its scope and now includes the examination of aviation, jet, Diesel and other fuel oils, petrol, lubricating oils, hydraulic fluids and solvents. Geological work included investigations of coal, clays, sand, water and miscellaneous mineral investigations, the major project being a survey along Evans-Thomas, Ribbon and Pigeon Creeks to determine coal measures in that area. Under the natural gas project for the conversion of carbon monoxide and hydrogen, from natural gas and oxygen, into a product resembling crude oil, the influence of operating conditions, catalyst structure and composition on the yields of liquid hydrocarbons was further studied, and a modified Emmett apparatus used to measure the surface areas of various catalysts. A market survey of poplar products was conducted, and the soil survey programme was continued in co-operation with the Dominion Department of Agriculture and the University Department of Soils. Tests were also made on the utilization of quartz sand and of straw.

Field Archæology in Great Britain

A NEW report, the "Survey and Policy of Field Research in the Archæology of Great Britain. 1: The Prehistoric and early Historic Ages to the Seventh Century A.D.", has recently been published by the Council for British Archæology, Institute of Archæology in the University of London (1948; price 5s.). The object of this publication is to consider briefly—in only 120 pages—the present state and future desirable direction of British field research. A number of archæologists have epitomized, without references, their present ideas about the periods under review and have pointed out where further work should be undertaken to settle doubtful questions and to fill in gaps. The idea of giving a present starting point and of suggesting where investigators should concentrate their efforts in the future is excellent. But it is not easy of execution. A volume issued under the auspices of the Council for British Archæology might be considered as indeed authoritative, yet the reader should remember that some of the statements made are really matters of opinion of the writers concerned and not universally agreed upon. For example, a number of investigators cannot agree with the statement at the top of page 21, and will affirm on the contrary that the industries in the top gravels of the 100-ft. terrace below London are indeed quite late and do belong to the same series as those from East Anglia mentioned at the bottom of page 20. Again, in such a short epitome is it not perhaps a pity to have introduced a totally new nomenclature for the glaciations which has not yet been to any extent accepted? The considerable cave excavations of Upper Palæolithic industries are dismissed in about three sentences, which is scarcely sufficient. The Neolithic Age is allowed three pages. Those who have studied the period will know the subject-matter already, while those who are less instructed will find the discussion far too condensed. But such a work lends itself to criticisms on almost every page, and yet undoubtedly it has a definite value. It covers a far wider range in time than most archæological works dealing with Great Britain, and in spite of criticisms of details, it does give a bird's-eye view of what is known of the period under review. The pin-pointing of what is required to be discovered by future investigators is also very useful.

Agricultural and Horticultural Research Station, Long Ashton

The annual report of the Agricultural and Horticultural Research Station, Long Ashton, for 1947 has now been published (price 10*s*.). The problems of the cider industry naturally play a prominent part in the work of the Station, and a list of suitable varieties for planting has been drawn up. Sweet and bitter-sweet sorts are specially advised, since many orchards at present contain too high a proportion of sharp varieties. Studies on the chemical composition of different ciders have been started and already fresh lines for further research work are indicated, which may well lead to results of practical importance. Another group of papers deals with the black currant crop. New varieties are described, and management and manurial treatment discussed. The nitrogen requirement of this crop is particularly high, and composts and stable manure alone have proved inadequate. Both fruit and vegetable crops are included in the investigations on plant nutrition. New methods have been developed for studying molybdenum deficiency in sand culture, while in the soil acidity investigations, some account is given of how the specific effects of aluminium toxicity, manganese toxicity, and calcium deficiency in various crops may be distinguished. As regards plant pests, a fluorine compound, *bis*-(β-fluoroethoxymethane), has been found to exert remarkable insecticidal properties, when watered on the soil, on beans and cauliflowers. Although compounds of this type cannot be used in commercial horticulture in view of their extremely poisonous nature, the discovery is of importance, for by it, light may be thrown on the process of translocation within the plant tissues.

Local Government

The problem of the definition of local government areas for one purpose or another is a very complex one. The needs of local administration have long outgrown the existing framework, and for every aspect of local government the boundaries need to be redrawn. In a paper in the *Geographical Journal* (111, 4–6) entitled "The Boundaries of Local Government Areas", Mr. E. W. Gilbert discusses some of the problems involved, especially as the geographer sees them, with reference to the "Local Government Boundary Commission Report" for the year 1946. A valuable feature of his paper is the series of twenty maps of England and Wales showing boundaries of areas that have been used or suggested for the different purposes, including gas and coal boards, electricity, railways, hospitals, post office, weather forecasts, and so forth. The divergence of views is obvious from these maps. Provinces or areas, each with a regional consciousness, do occur; there is no question of that; but the difficulty lies in their definitions. Even as regards towns the problem is not easy since town boundaries are arbitrary and do not coincide with the urban areas. Again, it is essential that the confines of an administrative region should embrace an area of which all parts are easily accessible in terms of time and expense. This feature has much to do with the growth of regional consciousness.

"Silva of North America"

"Silva of North America", the authoritative description of the trees which grow naturally in North America exclusive of Mexico, by Prof. C. S. Sargent, long out of print, has now been reprinted by Peter Smith, 321 Fifth Avenue, New York, 16, in a limited edition, complete with all the illustrations, in fourteen volumes (bound in seven) at 200 dollars net. Permission to reprint these books was granted to Peter Smith by Dr. E. D. Merrill, director of the Arnold Arboretum.

Announcements

Sir Edward Appleton, secretary of the Department of Scientific and Industrial Research, has been appointed principal and vice-chancellor of the University of Edinburgh. It has also been announced that Sir Edward has been awarded the Valdemar Poulsen Gold Medal of the Danish Academy of Technical Sciences, "for outstanding contributions to radio technics and particularly for remarkable achievement in research on the ionosphere". The award was instituted in commemoration of the work of Dr. V. Poulsen, the inventor of the Poulsen arc and a pioneer of radio-telephony, who received the first medal on the occasion of his seventieth birthday on November 23, 1939.

Mr. Roger Duncalfe has been elected chairman of the General Council of the British Standards Institution in succession to the late Sir Clifford Paterson.

The Council of Scientific and Industrial Research, India, has established an Indian Scientific Liaison Office in London, and Dr. S. Bhagavantam, who was professor of physics in the Andhra University, Waltair (India), has been appointed chief scientific liaison officer. This Office is with the Scientific Liaison Offices of the other Dominions, at Africa House, Kingsway, London, W.C.2.

The price of Richardson's "Veterinary Protozoology" reviewed in *Nature* of November 13, p. 756, is given as 10*s*. net. We are informed by the publishers, Messrs. Oliver and Boyd, Ltd., that the correct price is 18*s*. net.

A New Heterochromatic Fabry – Perot Fringe System Applicable to the Interferometry of Absorption Spectra

PARTIALLY successful attempts to apply the high resolving power of Fabry – Perot étalons to the study of astronomical absorption spectra have been made by Burns[1], Shane[2] and others. None of the arrangements hitherto employed has been successful in securing complete independence of the resolution from the slit-pattern distortion of the spectrograph, an effect which is always present in the high-dispersion spectrographs which these methods require for the primary dispersion.

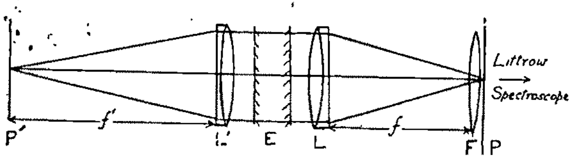

Fig. 1. Optical arrangement for the production of heterochromatic Fabry – Perot fringes

I have experimented with a new optical arrangement, which is depicted in Fig. 1. The Oxford solar spectrograph, a Littrow prismatic instrument with a dispersion of 1½ A./mm. and resolving power, not exceeding 10^6 at 5890 A., produced a spectrum of the solar centre in the plane *P*. Behind this plane was placed a second collimating lens *L* and a second camera lens *L'*. This system formed a second spectrum in the plane *P'*. The field lens *F* was introduced in the plane of the first spectrum *P* to obviate vignetting effects. When a small étalon was introduced into the parallel beam between *L* and *L'*, the second spectrum was broken up into a system of concentric circular interference fringes.

These figures resemble, superficially, normal Fabry – Perot fringes, but differ from them in three essential respects.

(1) The new fringe system is heterochromatic, being constructed of fringes of equal chromatic order. The large wave-length range over which the fringe system extends will be seen from the accompanying photograph (Fig. 2) of the *D* region.

(2) The centre of the pattern does not coincide with the axis of the étalon, but is displaced by an angle $f(d\lambda/dx)/\lambda$, where λ is the wave-length, f the focal-length of the second collimator, and $d\lambda/dx$ the dispersion at *P*. In view of the high dispersion of the Oxford instrument, and the short focal length (25 cm.) of the second collimator, this angle amounted to a few degrees only, a fortunate fact, to which the recognition of the fringe system was largely due. When the spectral region is altered by changing the setting of the minimum deviation link-work of the main spectrograph, the centre of the pattern becomes alternately bright and dark, and gradually shifts in relation to the étalon axis, in consequence of the varying prismatic dispersion.

(3) The intensity distribution within the fringes is a Fabry – Perot analysis of the instrumental slit pattern. Consequently a necessary condition for the production of the fringes is that the primary monochromatization produced by the main spectrograph shall correspond to a wave-length range smaller than the range of the étalon.

As a consequence of the third property of the fringes, the effect of widening the slit is to produce a pattern of much broadened fringes with an approximately square-topped intensity distribution. Within the fringes of this broadened system the solar absorption lines appear, broken up into short sections of Fabry – Perot ring systems of the normal monochromatic type, concentric with the axis of the étalon. The resolution of these absorption lines is completely independent of the instrumental slit pattern, and is entirely determined by the resolution of the étalon and plate-grain effects. The possibility of obtaining full resolving power with a wide slit, in contrast to Shane's method, allows a reduction of exposure time of the order of 100. Thus for the first time it becomes possible to make use of the high resolving power of really heavily silvered étalons.

The accompanying photograph of the *D* region was taken with a slit-width of 0·2 mm., étalon spacer 2·5 mm., reflectivity greater than 0·9. The exposure time was 13 min. Some idea of the actual improvement in resolving power will be given by comparing the interference photograph with the normal spectrum, taken with slit-width 0·025 mm. It will be seen that the line 5884, which is at the very limit of resolution in the normal spectrum, is very clearly split into two components in the interference photograph. This line appears single in Minnaert's photometric atlas, and is quoted in the Revised Rowland Catalogue as an iron line with a water-vapour companion too close for accurate measurement. The resolving power so far attained is provisionally estimated as about 400,000, and it is believed that the present limit is set by plate grain, owing to the somewhat short focal-length camera (50 cm.) thus far employed.

It is obvious that the method will be of wide applicability to problems of solar wave-length measurement, and to the photometry of absorption line contours. Plates for wave-length determination

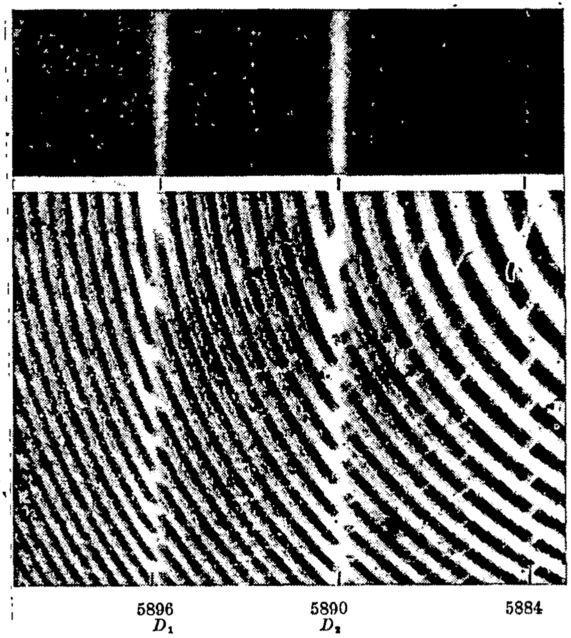

Fig. 2. Direct and interference photographs of the *D*-region of the solar spectrum (negative prints)

in the *D* region and for contour measurements of broad and narrow solar absorption lines in the region of the line Ca 4227 are now in process of measurement. A full account of the new fringe systems, and of these applications, will shortly be communicated to the Royal Astronomical Society.

Short-Period Changes in the *F* Region of the Ionosphere

Radio observations designed to detect horizontal movements in the ionospheric regions and to investigate the relation of these to previously observed changes occurring above a single observing point have been in progress for some months in the vicinity of Sydney, New South Wales. The present system uses three transmitters (T_1, T_2, T_3) placed at the apexes of a right-angled triangle with its shorter sides approximately north–south and east–west and of length 13 miles and 27 miles respectively (Fig. 1). The transmitters are operated on the same frequency and with the same repetition frequency, and are so phased, by either mains synchronization or pulse triggering technique, that the three pulses are spaced about 50 km. apart on a normal type of time base such as is used for ionospheric observations. It is thus possible to record the three sets of echoes simultaneously on a single film. Standard 35-mm. film is used, moved continuously with a film speed of ¾ inch per minute. Observations can be taken at one or more of three points, two being at the most widely spaced transmitting sites (R_1 and R_3), and a third at a point approximately midway between these (R_4).

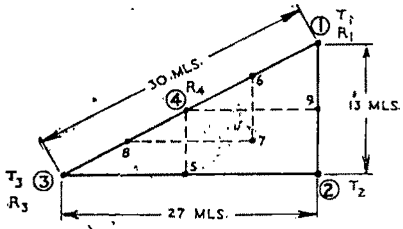

Fig. 1

Assuming that a reflexion point is vertically above a point on the ground midway between transmitter and receiver, we have eight possible points for checking uniformity of motion.

During seven months of operation (November 1947–May 1948), it has been observed very frequently that several types of clearly defined changes which occur in echoes from the *F* region show a time difference of occurrence at the spaced points.

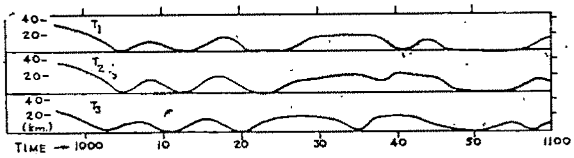

Fig. 3. Comparison of 'splits' observed at point R_3

Fig. 2 shows a particularly clear example of one type recorded at R_3. In this case the traces are produced by applying the signal to the intensifier electrode only of the cathode ray tube. The uniform lines are height marks spaced 100 km. apart. The top trace is the *F* region echo from transmitter T_3. The time base and height marker are initiated by this transmitter, so that the changes in virtual height are real.

The transmitters T_2 and T_1 are synchronized with T_3 through the 50-cycle power supply grid. Their traces (at R_3), therefore, show different amounts of phase fluctuation relative to T_3 and to the height marker, and their apparent changes in height may not be real. Corrections can be made if a ground ray is also visible on the screen; but this requires a closer scale with some loss of resolution. The transmitters T_1 and T_3 are interrupted for a few seconds at intervals of one minute (except every tenth minute on R_1), to provide time marks on the records.

It will be observed that there is a sudden disturbance on each trace in the form of a temporary splitting of the echo lasting about one minute (not easily seen in the reproduction). It occurs first on T_3, three minutes later on T_2 and a further minute later on T_1. An almost identical pattern was recorded four minutes later at R_1, which eliminates any possibility of the time differences being due to slight differences in frequency or to the small differences in the angles of incidence. The deduced direction of horizontal motion in this case is 60° east of north, and the velocity in this direction 3·9 miles per min.

Another common type of variation is shown in Fig. 3, which is a condensed plot of the amount of 'split' (difference in virtual heights of ordinary and extraordinary rays) for the three echoes as observed at R_3 over a period of one hour on the following day. It will be observed that quasi-periodic variations appear in almost the same form on all three traces, but with time differences which are of the same order as in Fig. 2.

Fig. 4 is a plot for the following hour of the virtual heights of the two components as observed at vertical incidence at R_3 and R_1. Here it will be seen that the two magneto-ionic components at each point (as shown by the full line and the dotted line) go through a very similar sequence of changes, but there is a time lag between the dotted and full-line curves. It will be noticed, however, that the time of travel from R_3 to R_1 is the same for both components. The time difference in this case is about seven minutes, as we are observing the full distance R_3 to R_1 and not the half-distance as in Figs. 2 and 3.

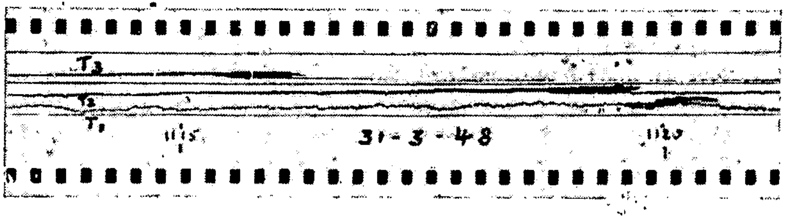

Fig. 2. *F* region echoes from spaced transmitters observed at R_3

We thus appear to have definite evidence of some form of horizontal progression in the *F* region. The great majority of cases analysed so far have given horizontal directions between 30° and 60° east of north, and deduced velocities between 3 and 5 miles

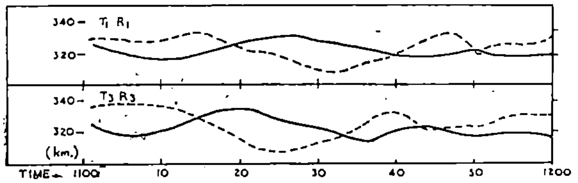

Fig. 4. Changes in virtual heights at points 1 and 3 (30 miles apart)

per minute. The observations have been made between 9 a.m. and 5 p.m. local time on a frequency of 5·8 Mc./s.

Changes in virtual height of the type shown in Figs. 3 and 4 appear most likely to be produced by changes in the ionization gradient. The effects observed might be due to either a horizontal drift in the atmosphere, with superimposed local variations in ionization gradient, or to progression of a wave motion of such a nature as to cause changes in ion concentration (for example, a pressure wave). Present evidence seems to favour the second alternative.

The time difference in the occurrence of the changes in the two rays in Fig. 4 suggests that there may be also a vertical component in the progression. This is supported by some $h'f$ observations which have been made at R_4 during occurrences similar to those of Fig. 4. They show a progression of such changes along the $h'f$ curve for the F region from the higher to the lower frequencies, corresponding to a progression from a greater to a lesser height.

Further observations are in progress to extend and clarify the information already obtained. The results will be reported more fully elsewhere.

This work has been carried out as part of the programme of the Radio Research Board of the Commonwealth Council for Scientific and Industrial Research, and is published with the consent of the Council. I wish to acknowledge the invaluable help of the staff of the Sydney Section of the Radio Research Board in carrying out the observations and to express appreciation of the keen interest of Sir John Madsen, chairman of the Board, which has made this work possible.

Evidence of Horizontal Motion in Region F_2 Ionization

DURING the winter periods of 1942 and 1943, a series of relative field-strength measurements were made at the Radio Research Station, Slough, on signals from the German short-wave sender Zeesen, situated 990 km. east of Slough[1]. Subject to the assumption that local time variations corresponded with longitude variations in the ionosphere, it was observed that the time of the initial appearance of the oblique ray signal at sunrise agreed closely with the value to be expected from calculations based on normal incidence ionospheric observations at Slough[2]. These sharp sunrise variations in the ionosphere occurred at Slough some thirty minutes later than at the mid-point of the oblique trajectory; this corresponds closely to the local time difference between Slough and this mid-point. It was noted, however, that in addition to these regular sunrise ionospheric changes of large magnitude, there were small irregularities in the F_2 layer occurring near the mid-point of the oblique trajectory, which were repeated overhead at Slough some 60–75 minutes later.

It is interesting to speculate on the reason for the repetition of small changes in region F_2 at two sites 500 km. apart along a line of latitude with a delay of one hour or more. It seems possible that the explanation lies in a rapid east–west motion of or within region F_2 ionization. An examination of many records indicates an average value of about 70 minutes for the delay time, requiring a velocity of 430 km./hr. in a direction east to west at the level of the F_2 layer at the time of such observations.

Latitude Effect of Penetrating Cosmic Ray Showers

IT has been shown by Broadbent and Jánossy[1] that penetrating cosmic ray showers are of two types: (*a*) local penetrating showers; (*b*) extensive penetrating showers. Local penetrating showers are supposed to be produced by primary nucleons, and they give rise to a transition effect which is proportional to mass. Extensive penetrating showers appear to be parts of extensive air showers. They show a strong transition effect in lead but almost none in paraffin.

From theoretical considerations, Jánossy[2] has suggested that local penetrating showers are produced mainly by nucleons that are latitude-sensitive. It is therefore expected that the transition effect of local penetrating showers might show a marked latitude effect.

In order to test this prediction, we have set up a penetrating-shower recorder situated at geomagnetic latitude 4° S. at sea-level in Colombo. This recorder is illustrated in Fig. 1 and is identical with that used by Broadbent and Jánossy[1] in Manchester. It consists of three trays of eight counters each, arranged as shown. Each tray covers an area of 1,000 cm.^{2}. The trays are separated by 15 cm. of lead absorbers, and in addition the middle and the bottom trays are shielded at the sides and ends by about 50 cm. of lead. The top tray is divided into three independent groups of counters, while the middle and the bottom trays are each divided into two groups as shown. Sevenfold coincidences (designated P) consisting of the simultaneous discharge of at least one counter of each group were recorded. These coincidences are due to the occurrence of showers of at least two particles capable of penetrating 30 cm. of lead absorber.

In order to select the local penetrating showers, a fourth tray of unshielded counters (not shown in the

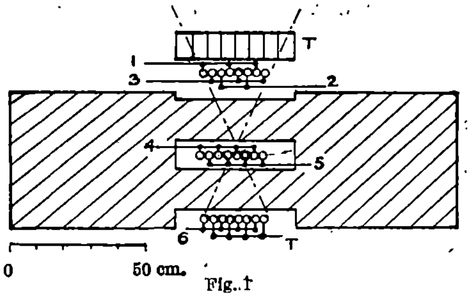

Fig. 1

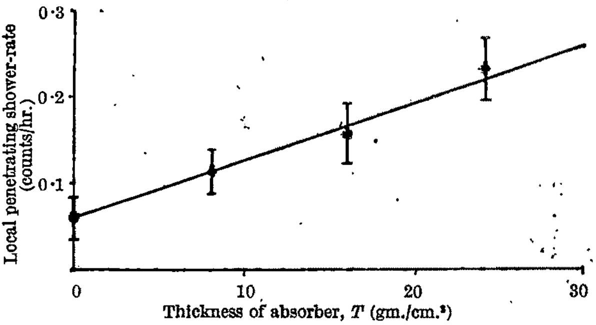

Fig. 2

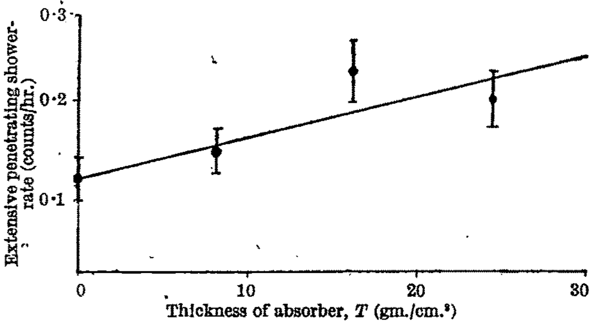

Fig. 3

figure) forming a single group of effective area 2,500 cm.^{2} was placed near the top tray. Eight-fold coincidences between *P* and at least one of the counters of the fourth tray were also recorded. These coincidences are due to extensive penetrating showers. Anticoincidences, that is, *P* coincidences not accompanied by the discharge of any of the counters of the fourth tray, are then due to the local penetrating showers.

We have in the first instance measured the transition effect in paraffin. Various thicknesses of absorber 48 cm. × 48 cm. were placed close above the top tray in the position *T* (Fig. 1). Our results are given in Fig. 2, the deviations shown being standard deviations. From a comparison of the results for Manchester and Colombo, we obtain the following values for the transition effect of local penetrating showers :

	Shower-rate for $T=0$ (coincid./hr.)	Initial slope of transition curve	Estimated max. shower-rate (coincid./hr.)
Manchester	$0{\cdot}051 \pm 0{\cdot}008$	$5{\cdot}7 \times 10^{-3}$	0·30
Colombo	$0{\cdot}060 \pm 0{\cdot}019$	$6{\cdot}7 \times 10^{-3}$	0·35

It is seen that the transition effect in Colombo is of the same order as that in Manchester. Hence there appears to be no observable latitude effect of penetrating showers. We have also measured the transition effect of extensive showers and found an indication of an effect in paraffin. The actual increase observed is from $0{\cdot}107 \pm 0{\cdot}026$ coincidences/hour without paraffin to $0{\cdot}208 \pm 0{\cdot}035$ coincidences/hour under 24·3 gm./cm.^{2} of paraffin. The effect is shown in Fig. 3.

It is hoped to publish elsewhere a detailed account of our work on completion.

Origin of Cosmic Rays

It is important to decide whether or not the main sources of the cosmic ray particles are external to our galaxy. An external source seems, at first sight, to be established by the observed isotropy of the cosmic rays incident on the earth. But it has been claimed by a number of authors that this isotropy is simply a consequence of a magnetic field assumed to exist in interstellar space. The basis for this claim is that a *single* particle of energy η and charge e is deflected through an appreciable angle after travelling a distance d across a magnetic field of intensity H, provided

$$H \sim \eta/ed.$$

For η equal to 10^{10} eV., e equal to the electronic charge ($4{\cdot}77 \times 10^{-10}$ E.S.U.), and d equal to the radius of the galaxy ($\sim 3 \times 10^{22}$ cm.), the necessary value of H is about 10^{-15} gauss. This value may be compared with the average interstellar field of about 10^{-20} gauss that would result if (i) every star possessed a magnetic moment equal to the commonly quoted magnetic moment for the sun ($\sim 1{\cdot}5 \times 10^{34}$ C.G.S.); (ii) the stellar magnetic dipoles were all aligned parallel to each other.

Although, even with these favourable assumptions, the interstellar magnetic field is still too small to be of consequence in this connexion (by a factor $\sim 10^5$), it has nevertheless been argued (*a*) that the magnetic moment of the sun may be exceptionally small, (*b*) that the connexion between angular momentum and magnetic moment suggested by Blackett[1] leads to an interstellar magnetic field $\sim 10^{-10}$ gauss. In view of these possibilities it is desirable to consider the matter afresh.

We find that the effects of a magnetic field as high as 10^{-10} gauss are still negligible. A fallacy underlies the usual type of argument, because the question cannot be decided through investigating the behaviour of an isolated particle. It has been shown that the motions of the cosmic ray particles are not appreciably disturbed by the field, provided

$$H^2 \leqslant 4\pi W,$$

where W is the energy density of the rays. Using the observed value $W \sim 10^{-13}$ ergs per cm.^{3}, this gives $H \leqslant 10^{-6}$ gauss, which is satisfied by a large margin even if Blackett's views are accepted.

The physical basis of the above inequality is easily understood. When this inequality is satisfied then, whatever the electromagnetic processes taking place within the particle distribution, the momentum density of a uniform beam of particles of energy density W is large compared with the average momentum density of the electromagnetic field. Our conclusion follows from the conservation of momentum, as applied to an assembly of particles moving in an electromagnetic field.

We see, therefore, that the main source of the cosmic rays must be external to the galaxy. An important consequence is that the source must be adequate to give an energy density $\sim 10^{-13}$ ergs per cm.^{3} not only in interstellar space but also in *inter-nebular* space. One of us[2] has discussed elsewhere the implications of this conclusion.

Effect of Hydrogen Atoms on Intensities of X-Ray Reflexions

In calculating the intensities of X-ray reflexions (diffractions) from crystals, it is customary to disregard contributions that may be due to hydrogen atoms. Their single electrons will tend to merge with the distributions about other atoms to which they are chemically bound, and the relatively small disturbance of the symmetry about these other atoms can usually be safely neglected.

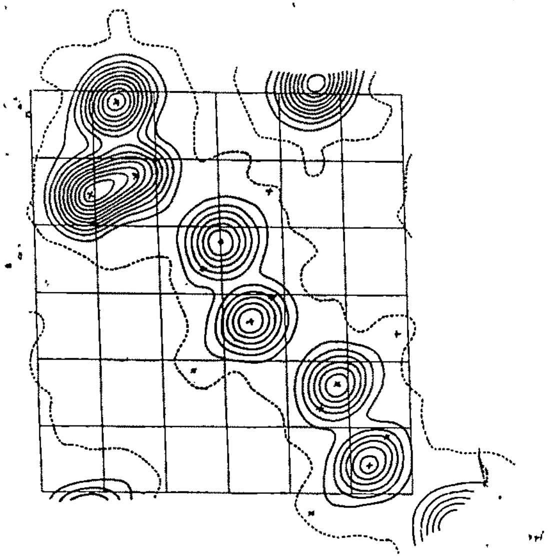

Fig. 1. Portion of sebacic acid structure. Contour scale, one electron per line

However, in discussing the results of some quantitative X-ray studies of aromatic hydrocarbons, especially coronene, $C_{24}H_{12}$, attention has been directed to certain small bulges on the electron density maps which appear close to every carbon atom to which a hydrogen atom should be attached[1,2]. Although these features are clearly visible, the total effect is too small to have much influence on the intensity calculations. If we regard the scattering power of the various atoms in a molecule as simply proportional to their atomic numbers, then the hydrogen atoms in the coronene molecule will represent only 7·7 per cent of the total scattering power. In pyrene, $C_{16}H_{10}$, the figure will be 9·4 per cent and in anthracene, $C_{14}H_{10}$, 10·6 per cent.

For aliphatic molecules, the total effect of the hydrogen atoms will be much greater. Thus, in methane the hydrogen electrons represent 40 per cent of the total, and in very long n-hydrocarbon molecules, C_nH_{2n+2}, about 25 per cent. We have recently been engaged on the detailed analysis of several aliphatic structures, and we find that it is necessary to take account of the hydrogen atoms in order to obtain reasonable agreement in the intensity calculations, particularly for the low-angle reflexions.

In sebacic acid, $C_{10}H_{18}O_4$, the hydrogen electrons account for 16·4 per cent of the total, and in hexamethylene diamine, $C_6H_{16}N_2$, 24·2 per cent. A detailed analysis of the crystalline structure of each of these compounds has now been completed, and the atomic positions have been determined accurately by the Fourier series method. The effect of neglecting the hydrogen contribution in calculating the structure factors for some of the low-angle reflexions is shown by the following figures:

046	0·588	6·1	6·9	3·3

In each case the hydrogen atom is assumed to lie at 1·09 A. from the carbon atom in the direction required by a tetrahedral distribution of the valency bonds. The atomic f-curve for hydrogen has been given the same general shape as the empirical f-curve for carbon[3], but with a more rapid fall-off at large angles. It is similar to Hartree's curve[4] but with a large temperature correction.

The electron density maps for these two molecules show the presence of the hydrogen atoms very clearly.

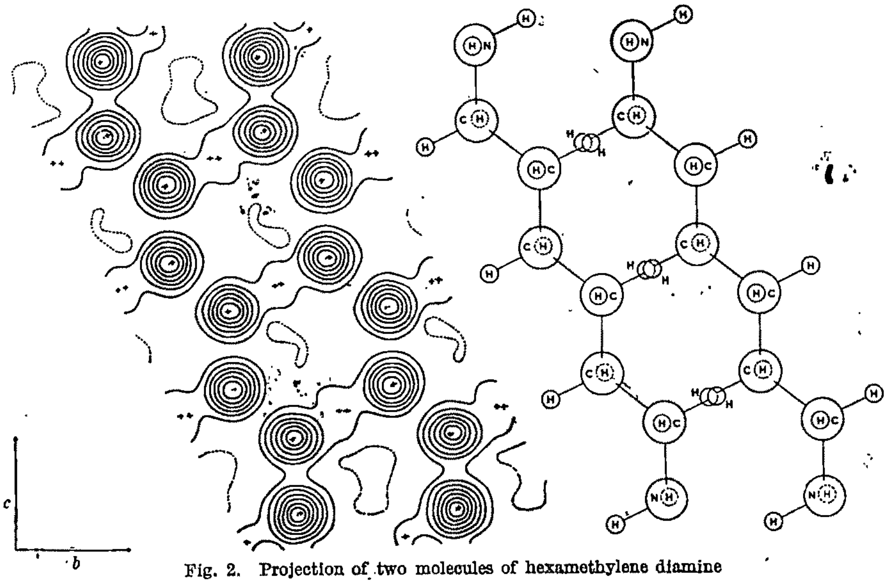

Fig. 2. Projection of two molecules of hexamethylene diamine

Four of the CH_2 groups in the sebacic acid chain are reproduced in a two-dimensional projection (Fig. 1), and the calculated positions of the hydrogen atoms are marked with small crosses.

In the hexamethylene diamine structure the crystalline arrangement of the molecules is particularly favourable for showing the hydrogen atoms in projection.

The molecules shown in Fig. 2 lie at different depths in the unit cell, but in projection the effect is to cause the hydrogen atoms of neighbouring molecules to overlap, with a consequent doubling of the projected electron density.

A Proposed New Form of Dielectric-loaded Wave-Guide for Linear Electron Accelerators

It has frequently been suggested that a linear accelerator could be constructed using a wave-guide consisting of a circular metal tube lined with an insulating tube of dielectric, and several writers have recently published theoretical investigations of this type of wave-guide, as, for example, Frankel[1]. The performance of a linear accelerator using such a wave-guide is ultimately limited by the power losses which occur in the metal tube and in the dielectric itself, and calculations show that the performance compares unfavourably with other forms of accelerator, such as corrugated wave-guides[2]. However, some recent theoretical investigations show that the performance should be greatly improved by using a different form of dielectric loading, and that certain practical advantages should also ensue.

It has been shown that the losses in the metal tube can be decreased by using an anisotropic dielectric with a smaller dielectric constant in the direction of the wave-guide axis than in the transverse directions. These properties may be simulated by using a stack of isotropic dielectric laminæ in planes perpendicular to the wave-guide axis, with suitable small spaces separating the laminæ from each other. Since it is necessary to have a central hole for the passage of electrons, each lamina will be shaped like an engineer's washer, and the whole will resemble a corrugated wave-guide in which the corrugations are made of dielectric. The thickness of the laminæ and their spacing should be small compared with the wave-length in the guide in order to simulate a homogeneous material. Laminating the dielectric reduces the power losses in the dielectric itself, in addition to reducing the losses in the metal through its simulated anisotropic properties, and the total losses are found to compare favourably with those in a corrugated wave-guide.

The following table gives a few computed examples for this type of anisotropic loading:

ε	Q	ε_p	a (metres)	b (metres)	L_0 (metres)	η (ohm/metre)
—	—	—	0·025	0·096	11	27×10^6
100	2,000	30	0·02	0·085	100	64×10^6
95	2,000	80	0·02	0·050	17	19×10^6
16	5,000	12	0·02	0·063	100	22×10^6
16	5,000	12	0·01	0·058	100	29×10^6

where ε is dielectric constant of solid (unlaminated) loading material; ε_p is effective dielectric constant in the radial direction; a is radius of central hole; b is internal radius of metal tube; L_0 is length of wave-guide with an attenuation of 1·25 nepers; η, the 'efficiency' or figure of merit, is $(0{\cdot}407)\, E^2/\alpha W$; E is accelerating field; α is attenuation constant; W is energy flux in the wave-guide; $Q = \omega\varepsilon/\sigma$ for the solid dielectric. All the examples are for a wave-length of 0·25 metres. The first row relates to a corrugated wave-guide with five corrugations per wave-length and twice theoretical copper losses. The remainder are for dielectric loading, in which the Q factor shown has been taken as about half that claimed for certain ceramic materials.

The dielectric system seems to have certain practical advantages compared with a corrugated wave-guide. The dielectric washers can be made from ground ceramic material, which is relatively inexpensive; and if the spacing between washers is adjustable there should be no need to maintain the very accurate dimensions which are required in the case of corrugated guide. The outside diameter of the dielectric guide is also smaller, which should again reduce the cost of an accelerator. Finally, the design of the dielectric guide is more flexible in that widely different characteristics can be chosen. There is, of course, a number of practical difficulties which may arise; but it is not anticipated that any of these will be very serious.

It is proposed to start some experimental work at the Telecommunications Research Establishment upon dielectric loaded guides to study their practical properties.

This work was carried out as part of the programme of the Electronics Group of the Atomic Energy Research Establishment at the Telecommunications Research Establishment, Malvern, and acknowledgment is made to Sir John Cockcroft for permission to publish the results.

Surface Effects with Single Crystal Wires of Cadmium

The letter of A. H. Cottrell and D. F. Gibbons, published in *Nature* of September 25, describes certain experiments which go to show that the phenomenon named 'thermal hardening' by Orowan[1,2], and recently investigated by C. L. Smith[3], is due to contamination by gaseous reaction. Experiments which we have been carrying out for some time on single crystal wires of cadmium have led us to the same conclusion. The surface of our *HS* cadmium wires, 1 mm. in diameter, was cleaned with great care, and single crystals were made by the method of Andrade and Roscoe[4], the wires being held in loosely fitting 'Pyrex' tubes which had been baked out at 400° C. and evacuated to a pressure of about 10^{-4} mm. mercury. Thus every precaution was taken against initial surface contamination.

Three pieces were cut from a single wire, of which one was kept as control, one for further heating *in vacuo* and one for heating in air. With no preliminary strain and heating for half an hour at 200° C. both in air and *vacuo*, no appreciable effect was obtained; while with heating for about 20 hours at 200° C. in air pronounced 'thermal hardening' appeared. If, however, one end of the wire, to the extent of a few millimetres, was momentarily immersed in a solution of cadmium nitrate and afterwards dried, so that strictly local contamination was produced, a heating for half an hour in air at 200° C. produced the hardening phenomenon. This leads us to the conclusion that the formation of the surface film, which would appear to be, in any event, the first stage in the process that leads to hardening, is very much facilitated by local contamination. We cannot say at this stage whether the local contamination be oxide, nitrate or other salt. The fact that the phenomenon is so dependent upon a slight *local* surface impurity of this kind no doubt explains the irregular results that have been obtained. We reserve further observations on the nature of the phenomenon for subsequent publication.

We take this opportunity of describing very briefly certain other experiments which we have been carrying out on the effect of surface conditions on mechanical properties of single crystals of cadmium. We have found, following extensive experiments on surface conditions, that, if a single crystal with a clean surface is loaded so that it flows very slowly (at a rate of about 1 per cent per hour), the surrounding of the wire with commercial cadmium plating solution (which contains potassium cyanide, cadmium potassium cyanide, sodium carbonate and sodium hydroxide) leads to an immediate increase of rate of flow, which may be anything up to twenty-fold. The fact that the effect is immediate seems to indicate that diffusion from the surface is not concerned. With a solution of cadmium sulphate an increase of rate of from two- to four-fold is obtained, both with unstrained crystal wires and with pre-strain of up to 30 per cent. Cadmium chloride solution produces a similar effect. With a solution of cadmium nitrate, however, an immediate increase is followed by a complete cessation of flow, the wire being brought to a state of such hardening that nearly double the initial stress is needed to start flow again. Preliminary experiments with zinc nitrate indicate immediate hardening. Similar results have been obtained with single crystal wires of commercial cadmium (impurity quoted by the suppliers as about 1 in 10^5, as against better than 5 in 10^6 for *HS* cadmium) surrounded by plating solution, whereas with polycrystalline wires of commercial cadmium no effect was obtained. At present we attribute the increase of rate to the action of the cadmium ions and the hardening to the formation of a surface film, probably of oxide. The work is continuing.

Strength of Metals

It has been shown previously that progressive deformation of an annealed metal breaks down the grains into smaller units, or crystallites, which have a minimum size characteristic of the metal[1,2]. The lower limiting size for metals so far examined lies in the range 10^{-4} to 10^{-6} cm. A precise determination of this size has become of importance, because it appears to coincide with the maximum strength developed during deformation of the metal[3].

Measurements can be made by the X-ray diffraction method, which utilizes the relation between broadening of the X-ray lines and the size of the reflecting units. Hitherto this method has been complicated by the extra broadening which occurs if the reflecting elements are in a different state of internal strain[4]. We have used the method but reduced the difficulty by two devices. First, we have confined the X-ray measurements to one direction in the metal at one time, thereby taking advantage of a recent observation that, in a systematically deformed metal, elements of the same orientation are in a similar state of strain. Secondly, we have been able to obtain X-ray back-reflexion photographs from the heavily deformed metals with much shorter wave-lengths than previously have been considered practicable, and, in this way, to distinguish the broadening due to small crystallite size, which is proportional to the wave-length, from that due to internal strains, which is independent of the wave-length.

The measurements have been made in the first instance on the body-centred cubic metals, iron, tantalum, molybdenum and tungsten, which respond particularly well to the above procedure. Thus, after deformation, these metals give very broad X-ray lines when photographed with a wave-length of the usual order, 1·5–2 A., but very much sharper lines when photographed with a wave-length of 0·5–0·7 A. The effect of small crystallite size can be shown, therefore, to be the predominant factor, and the size itself then calculated from the broadening without ambiguity.

Next, the values thus obtained have been related to the maximum tensile strength of the metals, on the general hypothesis that a metastable condition is reached when the overall elastic strain of the crystallite is equal to one interatomic spacing. The fractional strain is then of the order of d/L, where d is the atomic spacing and L the linear crystallite size; and the corresponding stress is this quantity multiplied by the appropriate elastic modulus. The maximum stress will arise when L has the minimum value given by the measured lower limiting size.

A detailed treatment, based on comparison of the energy of a crystallite before and after deformation by slip, has been given by Sir Lawrence Bragg, who obtains for the critical stress, kGd/L, where G is the shear modulus and k a constant of the order of unity[5]. This he identifies with the initial yield stress.

Much depends on the interpretation placed on the yield strength. A full discussion together with the experimental derivation of the minimum crystallite size will be given elsewhere. It is desired here, however, to record the values of the crystallite size and point out a close agreement between the quantity Gd/L and the maximum tensile strengths of the metals under consideration.

The values are given in the accompanying table. The figure taken for G for the metals iron, molybdenum and tungsten is the shear modulus in the

slip direction [111]. This figure is not available for tantalum, and for this metal the modulus measured on the bulk metal has been used. The value of d is the atomic spacing in the slip direction. The value L for the crystallite size is the minimum reached after progressive deformation, and thus refers to the fully strain-hardened condition. Exploratory measurements of L made some years ago by W. A. Wood were purposely confined to cold-worked metals in a partially recovered condition, and therefore gave somewhat larger values. The present values for L are the ones required for comparison with the maximum strength. The table includes observed values of true tensile strengths (S obs.). The value for the iron was determined directly; the remainder were taken from published data. Unfortunately, the figures usually published are nominal strengths calculated on the initial cross-section of the test specimen, or, for the rarer metals, strengths measured on hard-drawn wires, which often are in a state of high internal strain. The values given in the table, however, suffice to indicate that the calculated strengths S (calc.) $= Gd/L$ are definitely of the right order.

Production of Extremely Thin Metal Films by Evaporation on to Liquid Surfaces

In two articles in *Nature* of March 15, 1947, a method is given for making very thin metal films, 10–20 A. or more in material thickness. On the surface of a film of cellulose nitrate, etc., there is evaporated a small amount of, for example, beryllium or aluminium. Then the basic film is dissolved away by amyl-acetate or other appropriate solvent, the metal being left free. Such films of beryllium or aluminium are especially useful as supporting membranes for electron microscopical studies. As a rule these metal films have no visible structure. It may, however, happen that a faint structure appears even if the film is very transparent in the electron microscope. This structure effect may depend upon the fact that all the cellulose molecules are not nitrated to the same degree, some of them being insoluble in amyl acetate. Other explanations may be that a molecular layer of the cellulose nitrate adheres very closely to the metal surface and does not go into solution, or that some of the very active metal atoms have penetrated into the cellulose molecules. I have now found that the structure effect mentioned above does not exist when using acrylates instead of cellulose nitrate, collodion, etc., as the basic film. The solvent then used is ethyl acetate. The metal films made are almost invisible in the electron microscope when made 20 A. in thickness, and the photographic contrast effect of the object particles is increased compared with that obtained with ordinary supporting membranes, which is of the greatest importance when studying molecules or other minute particles.

I have recently devised another method for making thin metal films, which is simpler, since no dissolving process is needed for the basic film: *the metal film is made by evaporation in a vacuum of a small amount of beryllium or aluminium on to a liquid surface.* From the physical point of view it may seem impossible to get any metal layer in this way. It works nicely, however, and very thin films of beryllium and of aluminium can be made. I have been using several liquids, but chiefly glycerol. The liquid used must have a high boiling point and low vapour pressure at room temperature; for example, glycerol, boiling point 290° C. and vapour pressure less than 10^{-4} mm. mercury.

The procedure for making metal films on a glycerol surface is as follows. A piece of glass, about 3 cm. × 3 cm., is covered with a thin layer of glycerol ($\frac{1}{2}$ mm. or less in thickness) and put into the vacuum chamber. The glycerol ought not to have more than the smallest possible content of water, otherwise it will boil in vacuum. After a little while, when water which may have been absorbed in the glycerol has disappeared, a small amount of metal (beryllium or aluminium) is evaporated. The glass slope is next put into a container into which distilled water is introduced. The glycerol is dissolved and the film will immediately float off; it lies on the water surface, holding together well. The film is washed by using a container, where the water can be changed without disturbing the film. The film is transferred to a plane grid of copper, platinum or other convenient metal, the holes measuring about 0·1 mm. in diameter, and is allowed to dry. In this way it is easy to get pieces 3 cm. × 3 cm. or more, and whenever a specimen film is needed, a little piece can be cut off this ready-made film.

It is possible to make membranes of beryllium, aluminium, etc., with a material thickness of only 10–20 A., lying on grids where 80 per cent of the area is covered with only the thin metal film. Such thin films are of great interest also from the physical point of view, especially in investigations on the scattering effect of electrons penetrating thin metal films, and the contrast effect in the electron optical picture. One of the greatest advantages of this new method compared with the old method of making metal films for electron microscopical use is the possibility of laying a metal film directly on an organic substance without using amyl acetate or other liquids which affect organic substances.

I have also evaporated metals on to oil surfaces (vacuum oil); but in this case I did not obtain metal films; but there seemed to be rather big metal crystals after dissolving away the oil. According to the atomic structure of the liquids used, it may be expected that the active metal atoms are more likely to penetrate into the oil surface layer than into an ordinary liquid.

In another experiment I have evaporated aluminium metal in a vacuum on to a mercury surface. It is well known to chemists that mercury and aluminium react readily, when put into contact, growing salt-like trees at reaction points. The very unexpected thing is that this did not take place when I evaporated aluminium on to a mercury surface in vacuum. It may depend upon the fact that the evaporated aluminium atoms cannot penetrate into mercury—possibly the surface tension will not let them penetrate, on account of crystalline structure of the liquid in the surface or in the mass itself.

When beryllium is being used, great care must be taken, due to the fact that beryllium dust has been found to be very poisonous.

The investigations described above were carried out at the Nobel Institute for Physics in Stockholm.

'Knock' in Internal Combustion Engines

THERE is evidence that the phenomenon of 'knock' in spark-ignition engines is connected with the production of peroxides in the last part of the fuel–air mixture to be burnt. Thus we have found that of all the intermediate products of combustion which have been identified in the gases sampled from the engine, the peroxides are the only ones which possess an appreciable pro-'knock' effect. Egerton *et al.*[1] have shown that peroxides, probably alkyl hydroperoxides, are present in the pre-combustion processes, and Stern and Polliak[2] have identified hydrogen peroxide in samples taken from an engine cylinder. This work has now been extended to enable quantitative determinations to be made of the total peroxide content of gas samples. At the same time, we have determined the aldehyde content.

An electromagnetically operated valve has been developed which permits samples to be abstracted from an engine cylinder over a narrow crank period. This is used on a Ricardo E6 variable compression engine and positioned so that gas is sampled from the 'knocking' zone. At an engine speed of 1,500 r.p.m. and a valve opening period of 3° crank, a flow-rate of 200 c.c./min. of expanded gas is obtained when sampling at about the time of maximum cylinder pressure.

Secondly, we have developed a method for the determination of the total organic + hydrogen peroxide content of the sampled gases. The major difficulty is the presence of nitrogen dioxide and olefins, which obviously complicate any such determination. Our method, which is basically that of iodine liberation from potassium iodide, is as follows. The nitrogen dioxide is removed by passing the sampled gas through a trap containing an aqueous solution of sulphamic acid. This retains the peroxides in solution and at the same time destroys the nitrous acid formed from the nitrogen dioxide which otherwise would reduce the peroxides. The olefins are removed by bromine under conditions designed to minimize the loss of peroxide by interaction with bromine. Ferrous sulphate is used as a catalyst in the reaction with potassium iodide.

Thirdly, we have used essentially the bisulphite method of Lea[3] to determine the total aldehyde content.

Peroxide curves obtained using technical *iso*-octane as fuel are shown in Fig. 1. At the lower compression ratios, the engine was free from 'knock', while at a compression ratio of 9·9, 'knock' of a fairly heavy intensity occurred. On all these curves a rise in pre-flame peroxide concentration takes place prior to 'top dead centre', followed by a much higher peak value just before the flame. With increase of compression ratio there is an earlier rise in peroxide concentration and a much higher peak value. Surveying the large number of these curves which we have obtained there appear to be indications of a slight discontinuity just after 'top dead centre', suggesting that the curves are two-stage in nature.

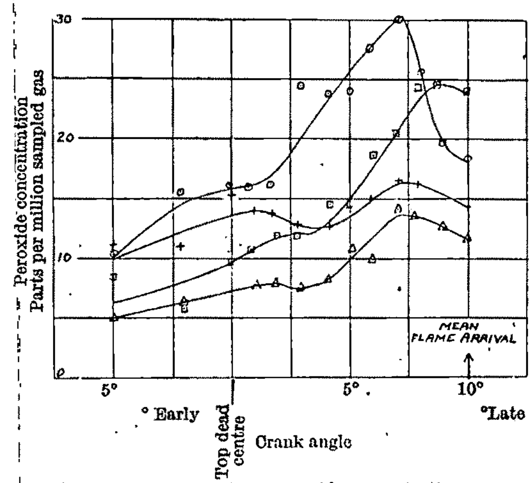

Fig. 1. Pre-flame peroxide concentration

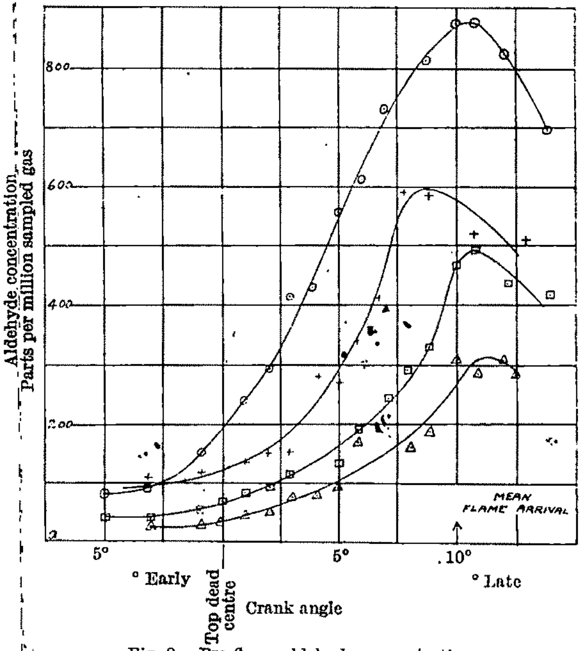

Fig. 2. Pre-flame aldehyde concentration

	Compression ratio	Fuel
△ — △ —	7·0	Octanes
□ — □ —	8·0	Octanes
⊙ — ⊙ —	9·9	Octanes 'knocking'
+ — + —	9·9	Octanes + 3 c.c. T.E.L./I.G.

The effect of the addition of tetraethyl lead to suppress 'knock' is to lower the concentration of peroxides, as compared with the curve on the unleaded fuel at the same compression ratio. The effect appears to be greater after 'top dead centre' than before, thus tending to confirm the two-stage nature of the curves.

The aldehyde curves (Fig. 2) show a smooth rise up to the time of flame arrival, achieving a peak concentration some thirty times greater than the peak peroxide value. The effect of increasing compression ratio on the aldehyde concentration parallels the effect on the peroxide curve. Tetraethyl lead uniformly decreases the aldehyde concentration at all points.

As regards the nature of the aldehydes produced, repeated tests with dimedone gave only the formaldehyde derivative.

Infectious Chlorosis of Bananas in the Cameroons

During recent years, there has been a considerable extension of the cultivation of the Gros Michel banana in the British Cameroons. Vascular wilt disease (*Fusarium oxysporum cubense*) and *Cercospora* leaf-spot disease (*Cercospora musæ* Zimm), which are both present there, are already well known to the planting community. Here I wish to direct attention to a virus disease which I observed during a recent visit. This disease, which has been described as 'infectious chlorosis' or 'heart rot' by Magee[1] and Morwood[2], has been recorded in New South Wales by these observers[3] and in Guadeloupe and Haiti by myself[4,5].

In the Cameroons, infectious chlorosis has been observed in several plantations. The virus is known to be transmitted by the aphis *Pentalonia nigronervosa*[1]; this is also present. According to the Australian workers, this disease is potentially as destructive as the better-known bunchy-top disease, caused by a different virus but also transmitted by the banana aphis. In the Cameroons the evidence (so far as I was able to ascertain during a brief visit) is that infectious chlorosis is at present of occasional occurrence but is capable of spreading under the local environmental conditions. Accordingly, Magee's warning of the possible destructiveness of this disease should be given due heed by all concerned with this valuable industry.

The symptoms include a characteristic chlorosis of the leaf (linear spots from midrib to margin), the development of localized, internal regions of necrosis in the leaf sheaths of the trunk, rotting of the heart leaves and the death of the plant before the onset of fruiting[3].

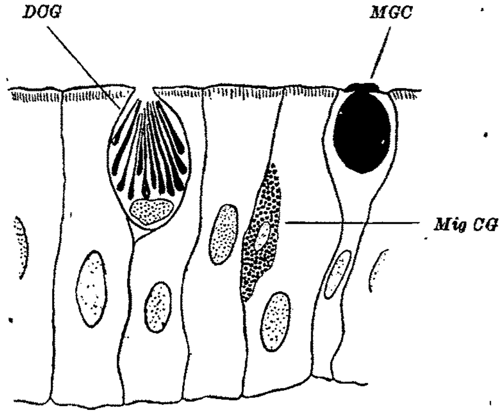
Coarse Granulocytes in Epithelial Tissues of Teleost Fishes

In the course of an investigation of blood-cell formation in teleost fishes, a peculiar formation has been seen in the intestinal mucosa and gill epithelium. Apparently the coarse granulocytes commonly found in these tissues migrate towards the surface and the granules elongate, appearing like long narrow clubs with pointed ends converging towards the epithelial surface. This regular characteristic pattern of arrangement was first noted by Duthie[1] in the mesenteries of teleost fishes of the families Labridæ and Triglidæ. I have seen it in the intestinal mucosa and gill epithelium of *Ctenolabrus rupestris* (Labridæ) and *Trigla cuculus* (Triglidæ), and also in the same sites in trout and roach. In trout and roach I have observed similar formations in the walls of kidney tubules and in the peritoneal coat of many internal organs.



Intestinal mucosa of trout. Fixed Zenker-formol. Stained Giemsa
DCG = Discharging coarse granulocyte; *MGC* = mucous goblet cell; *Mig CG* = migrating coarse granulocyte

Careful examination of dogfish, frog and mammalian material has not revealed a single example of such a condition. The appearance suggests a discharge of a fluid substance from the interior of the granules. These modified granules may be regarded as vesicles, containing a fluid which is discharged at the epithelial surfaces detailed above, the 'wall' of the vesicle remaining for a time in the cell body.

Burrowing of the Lugworm

In his recent letter in *Nature*[1], Wells gives an interesting account of the movements and action of the proboscis of the lugworm and of the part that it plays in burrowing. He considers that its movements alone are sufficient to account for this activity, which is chiefly due to the diverging teeth of the buccal mass scraping away soil particles in the line of advance. He appears to consider that the physical properties of the soil are of no direct importance to burrowing, which he likens to that of a "digging rabbit".

But it appears to us that the mode of action of the proboscis described by Wells is in no way at variance with our thesis, namely, that the thixotropic properties of the soil must be taken into account to explain satisfactorily the burrowing of the lugworm, and probably that of other animals living in a similar habitat. The exact movements of the proboscis, interesting though they are in themselves, are but a means of softening the soil in the line of advance. That a mere scraping away of sand particles is insufficient to account for the burrowing of the creature is shown by the results of other experiments (in the press). These indicate that the thixotropic state of the muddy sand which we studied is dependent upon the water content, and if this is reduced below a certain value (about 25 per cent by weight of water in the whole mass) the ability of the sand to become fluid on agitation is so diminished that lugworms cannot burrow into it. Yet, if we understand Wells' argument correctly, there should be nothing to prevent lugworms from burrowing even into perfectly dry sand. This they cannot do, nor, in fact, into sand which is not fully saturated with water.

Another aspect which is accounted for by the thixotropic behaviour of the sand is the construction by the worm of a *permanent* L-shaped burrow, as described fully by Wells[2]. This permanence could be accounted for by the rapid setting of the sand, as soon as the movements making the burrow have ceased. Again, it can be assumed that the downward-moving column of sand filling the headshaft is produced by movements which are effectively similar to those by which the burrow was made in the first place.

The Cellulose of Marine Algæ

THE term 'algic cellulose' was applied by Stanford[1] to an insoluble residue obtained from seaweeds after the removal of algin, and many workers have assumed that this material is identical with the cellulose of land plants. Although denied by some[2], this view has been supported by Kylin[3] on the evidence of the colour reaction with iodine and sulphuric acid, and by Russell-Wells[4], who also demonstrated the solubility of the material in cuprammonium hydroxide and prepared an acetate.

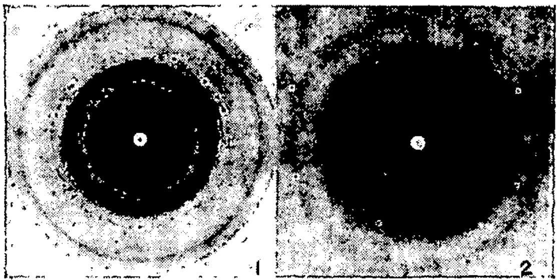
Dillon and O'Tuama[5] obtained a sugar by hydrolysis from which they prepared glucosazone and showed also that 'algic cellulose' was not a mannan. It was also converted into a viscose and into chloroform-soluble acetyl and methyl derivatives.

From these qualitative tests, therefore, the possibility exists that 'algic cellulose' is similar to cotton cellulose; but no evidence is available to show either that the substance is built up entirely from glucose residues, or that the fundamental 1,4-β-linkages are present. The problem has now been reinvestigated under the auspices of the Scottish Seaweed Research Association.

Algal celluloses have been prepared from *Laminaria Cloustoni*, *L. digitata* and *Fucus vesiculosus* by a method based on the A.O.A.C. (Washington) crude fibre determination[6]. The products gave the characteristic blue colour with iodine–zinc chloride, and dissolved readily in Schweizer's reagent. Fluidity measurements[7] gave a value of *c.* 40 poises^{-1} and indicated considerable degradation in comparison with cotton cellulose (*c.* 2 poises^{-1}); a control experiment showed that this high fluidity was due mainly to the rather vigorous treatment used in the isolation, since the fluidity of cotton cellulose rose from *c.* 2 to 28 poises^{-1} when treated similarly.

Hydrolysis to glucose (yield 80 per cent of the theoretical, cf. 88 per cent from cotton cellulose) was carried out by the method of Monier-Williams[8], the sugar being estimated both polarimetrically and by Somogyi's[9] method before and after treatment with yeast[10]. No other reducing sugars could be detected, and this was confirmed by the paper chromatogram. Glucosazone was isolated in the usual way.

The algal cellulose was converted into cellobiose octa-acetate[11] (yield, 31 per cent); m.p. 224°, not depressed on admixture with an authentic specimen, $[\alpha]^{20°}_{D}$ + 40° (in chloroform). This is strong presumptive evidence that 1,4-β-linkages are present, and further confirmation was obtained by periodate oxidation. The course of this reaction was the same as that followed by cotton cellulose, 1·02 mol. of sodium periodate being consumed per $C_6H_{10}O_5$ unit (constant after seven days). The possibility of the existence of 1,3- and 1,6-linkages is thus negatived, since in the former case none, and in the latter two, molecules of $NaIO_4/C_6H_{10}O_5$ would be required, apart from the requirements of the terminal groups.



X-ray diagrams of (1) algal cellulose from *L. Cloustoni*, (2) material regenerated from (1) after dissolution in cuprammonium hydroxide

Oxidation with potassium periodate[12] and titration of the formic acid released (fourteen days) gave a result corresponding to a chain of *c.* 160 glucose units. This is much less than the value reported for cotton cellulose, but is explained by degradation during isolation. This result also disposes of any possibility that significant numbers of glucose residues are united in the polysaccharide by 1,6-linkages.

Through the kindness of Prof. W. T. Astbury, the X-ray diagrams of an algal cellulose prepared from *Laminaria Cloustoni* (Fig. 1) and of the material regenerated from *A* after dissolution in cuprammonium hydroxide (Fig. 2) have been investigated. *A* shows the characteristic pattern of normal cellulose and *B* that of 'hydrate' cellulose.

This result, taken in conjunction with the chemical evidence outlined above, makes it certain that algal cellulose is fundamentally similar to the cellulose of land plants, although, as with the cellulose from different plants, it would be unwise at present to assume that all celluloses are identical in every respect.

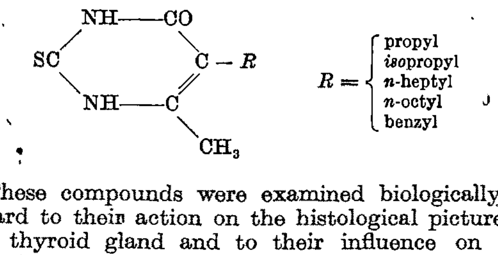
Effect of 5-Alkyl (Benzyl) Derivatives of 2-Thio-4-Methyl-Uracil on the Thyroid Gland and the Bone Marrow in Rabbits

H. Cullumbine and M. Simpson[1] have reported the results of their investigations on the activity of several derivatives of thymine (5-methyl-uracil) having an antithyroid property and a stimulating action on the bone marrow. These researches were based on the assumption that if thymine, according to Spiess, Jacobson and Williams, possesses a therapeutic value in the treatment of pernicious anæmia, its thio-derivatives should have a similar property with the simultaneous antithyroid activity. It is known that one of the greatest disadvantages of antithyroid drugs now being used is their toxic effect on the functioning of the bone marrow. The quantitative changes of reticulocytes and leucocytes in normal and splenectomized rabbits after a parenteral treatment with the compounds being tested were the basis of Cullumbine and Simpson's investigations.

The thiouracil derivatives synthesized by me in the Biological Institute of the University of Kraków possessed various hydrocarbon radicals (*R*) in position 5 beside the methyl grouping in position 4.



These compounds were examined biologically in regard to their action on the histological picture of the thyroid gland and to their influence on the functioning of the bone marrow. The criterion of the latter in my work was the number of white blood cells in 1 mm.^{3}. The animals used were white rabbits about eight weeks old. All the compounds tested were given by mouth in equal dosages, once daily and for equal periods, to facilitate the comparison of the results obtained. The animals were treated in three groups: group (I), 9 days with 50 mgm. a day; group (II), 9 days with 50 mgm. a day and the following 5 days with 100 mgm. a day; group (III), 9 days with 50 mgm. a day and the following 9 days with 150 mgm. a day. In this way the following compounds were tested biologically: 2-thio-4-methyl-uracil; 2-thio-4-methyl-5-propyl-uracil; 2-thio-4-methyl-5-*n*-heptyl-uracil; 2-thio-4-methyl-5-*n*-octyl-uracil; 2-thio-4-methyl-5-*iso*propyl-uracil; and 2-thio-4-methyl-5-benzyl-uracil.

The first compound (May and Baker, Ltd.), at present widely used in the treatment of all forms of thyroid hyperfunction, was used as a standard preparation for comparison purposes. The results are given in the accompanying table.

Name of compound	Average percentage change in white blood cell count	Histological activity
2-Thio-4-methyl-5-propyl-uracil	−30	+++
2-Thio-4-methyl-5-*n*-heptyl-uracil	+64	no effect
2-Thio-4-methyl-5-*n*-octyl-uracil	+66	no effect
2-Thio-4-methyl-5-*iso*propyl-uracil	+52	+
2-Thio-4-methyl-5-benzyl-uracil	+15	+
2-Thio-4-methyl-uracil	−28	++++

Comparing the results, it is clear that the greater the number of carbon atoms in the *n*-radical linked with position 5, and consequently the larger the molecular weight of the whole compound, the weaker its antithyroid activity and the greater the stimulating effect on the bone marrow. The decrease of the antithyroid activity in this group of derivatives is, I think, connected with the increase of the molecular weight of the compounds, and consequently with decrease of the percentage of sulphur in the molecule.

In the second group of compounds tested there is an interesting difference between the 2-thio-4-methyl-5-propyl-uracil and 2-thio-4-methyl-5-*iso*propyl-uracil. The former exerts a marked influence on the function of the thyroid gland and an inhibiting one on the bone marrow, whereas the latter with its small effect on the thyroid gland brings about a rise of the white blood cells count of about 52 per cent.

Of the aromatic derivatives of 2-thio-4-methyl-uracil only the benzyl compound was tested; it was found to be ineffective as regards both the thyroid and the bone marrow.

These results show that the pharmacological action of these compounds depends not only on the number of the carbon atoms but also on the configuration of the radical linked with position 5. Further derivatives of this type are being prepared and tested.

Role of Gastric Urease

IN a previous communication[1], we were able to confirm that urease is present in the gastric mucosa and, to some extent, in the duodenal mucosa. It was pointed out that the amount of the ferment present in the whole stomach of an animal is sufficient to release enough ammonia from urea to neutralize large amounts of hydrochloric acid.

We suggested previously that urease might be concerned with the protection of the superficial gastric mucosa and the neutralization of hydrochloric acid, a view of its possible purpose which has also been advanced in the past by Luck[2], Linderstrøm-Lang and Ohlsen[3] and others. No direct experiments on this point were ever apparently made. If the concentrations of the substrate, urea, were changed, presumably there might be more ammonia formed. In a series of normal student subjects we have compared the response of the stomach to histamine stimulation when given either without or with urea administered orally. The results are summarized in the accompanying table. It should be emphasized that all the urea solution was removed as the first post-histamine specimen was being removed, and, of course, that in the non-urea series a control solution was administered at zero time.

Mean maximum secretory response of 14 normal human stomachs to histamine acid phosphate (0·1 mgm./10 kgm.) without and with 15 gm. urea given at time of injection

Hydrochloric acid (m. eq.)				Ammonia-nitrogen (m. eq.)				
Non-urea		Urea		Non-urea		Urea		Blood urea change (mgm. per cent)
Fasting	After histamine	Fasting	After histamine	Fasting	After histamine	Fasting	After histamine	-
5	60	6	27	9·36	9·80	7·99	36·54	29 → 41

These results are qualitatively similar in a limited series of gruel test meals or insulin test meals. The invariable result is a reduction of hydrochloric acid only variable in degree. It might be noted that even at the height of ammonia release into the stomach, the degree of neutralization observed could not always be explained on the basis of intra-gastric ammonia alone. The maximum increase in blood urea in these cases falls almost within the range noted after a meal (cf. Conway, O'Connor and O'Donovan[4]). We are, as yet, not clear how the precise effect of the urea rise is brought about, though the neutralization view is most favoured. There is a possibility that the increased urea inhibits the oxyntic cells. Against this there is the observation that the histamine volume response does not appear to change, suggesting the effect is eventually increased neutralization rather than diminished formation.

A calculation can be made as to the amount of urea which would be required to neutralize an average amount of acid secreted in the stomach. Urease releases 2 mol. of ammonia from 1 mol. of urea. At *p*H 6, 80 per cent of the ammonia nitrogen released from urea by urease will be dissociated from any HCO_3 compound; at *p*H 5 about 95 per cent will be dissociated. 300 mgm. urea would be required to neutralize 100 ml. $N/10$ hydrochloric acid. It is known that there may, at least in extreme circumstances, be quite a large urea A/V difference in the stomach (cf. Vladesco *et al.*[5], who were only concerned with the problem of urea excretion in uræmia). No figures are as yet available for animals with a more normal blood urea, nor are there any reliable data on the blood flow in the stomach. Hanke[6] states that 60 ml. of gastric blood flow is required for the production of 1·1 ml. of gastric juice. If the same flow exists during the time required to neutralize this same acid (assuming it to be $N/10$) an A/V difference of 5·5 mgm. per cent urea would be required. Obviously the addition of urea would facilitate this effect, though how it is controlled we do not know.

We have no evidence as to the fate of any ammonia retained inside the gastric mucosal wall, but have not been able to detect any urea-forming system. The use of urea in the study and treatment of the peptic ulcer has been initiated and the results to date are most promising.

One of us (O. F.) wishes to acknowledge the receipt of grants from the Medical Research Council of Eire. We would also wish to acknowledge our indebtedness to Prof. E. J. Conway for many helpful discussions.

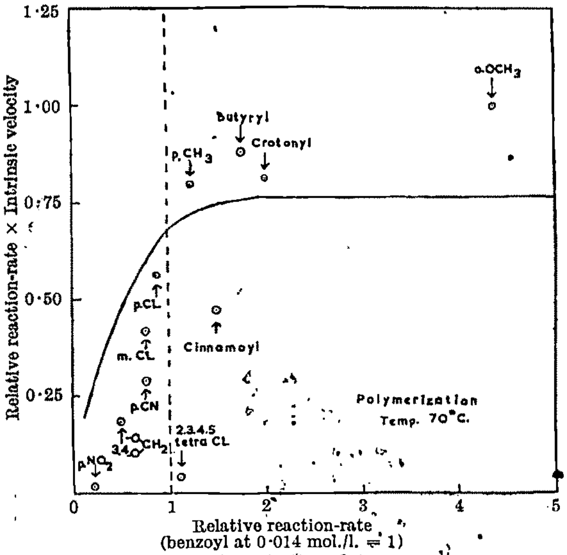
Radical Reactivity in the Initiation Reaction of the Polymerization of Styrene

FREE radicals are known to have widely varying activities, as shown by the studies on the reactions of peroxides with various organic compounds by Kharasch[1] and by studies on copolymerization by Mayo *et al.*[2]. It is possible from a study of the catalysed polymerization of vinyl compounds to obtain information on the activity of the radicals initiating the polymerization. Results are here given on the polymerization of styrene using various types of peroxide catalyst. As an empirical and arbitrary measure of the activity of the catalyst, the product of the rate of polymerization and intrinsic viscosity of the polymer has been taken. (The detailed justification for holding this to be a measure of the catalyst activity will be given on another occasion.)

In the accompanying graph are shown the results obtained with a few diacyl peroxides. The product of $-\frac{dM}{dt} \cdot (\eta)$ is plotted against $-\frac{dM}{dt}$ (the velocities of reaction are taken relative to that of benzoyl peroxide at 0·014 mol./l. concentration; the other peroxides examined are at the same concentration).



Bulk polymerization of styrene

The continuous line shows the value of $-\frac{dM}{dt}\cdot(\eta)$ for benzoyl peroxide over a wide range of concentrations. This has been included as it shows that with 'good' catalysts and fairly high catalyst concentrations the activity is independent of changes of catalyst concentration. This point is important since all peroxides decompose at different rates; hence the comparison has been made at equal rates of polymerization. The fall in the curve at lower concentrations is probably due to the more noticeable effect of transfer reactions. (As at this stage the results are purely comparative, it is not considered necessary to use the power relationship which has been established between (η) and the molecular weight; the constancy of the product of the reaction-rate and intrinsic viscosity over a wide range is fortuitous.)

The activity, according to this point of view, is shown by the values of the ordinates for the various catalysts relative to the standard catalyst, benzoyl peroxide. The position on the abscissa is of less importance, though in some cases it gives an indication of the rate of decomposition of the catalyst. The results shown, which are mainly obtained from substituted benzoyl peroxides, support the view that electron-attracting substituents give radicals of low activity, particularly when this is supplemented by the mesomeric effect. On the other hand, electron-repelling groups increase the activity of the radical.

In the case of alkoxy benzoyl peroxides, the mesomeric effect outweighs and reverses the inductive effect, consequently the activity of the radical is high. (This result is supported by U.S.P. 2,419,347, claiming high catalytic activity for *o*-alkoxy benzoyl peroxides.) However, di(3-4-methylene dioxybenzoyl) peroxide has a low activity, suggesting that the observed effect is purely inductive. Halogens have similar activities with the same orientation: the two results shown for di-*p*- and -*m*-chlorobenzoyl peroxides are in the expected positions. (Many of the results are in a similar order to those found for the dissociation constants of the substituted benzoic acids. In addition, an 'ortho' effect is shown by all ortho-substituted benzoyl peroxides.) Alkyl groups, as would be expected, increase the activity; but there is little difference between the effects of different alkyl groups. A result for an aliphatic acyl peroxide is given, and, as would be expected, this shows high activity. The introduction of a double bond (dicrotonyl peroxide) increases the rate of reaction, possibly by an increase in the rate of decomposition, and causes a slight fall in activity. Replacement of the methyl in this peroxide by phenyl, however, in dicinnamoyl peroxide, stabilizes the radical, which is consequently of lower activity.

These results seem to indicate that an important characteristic of a free radical is the availability of the free electron for reaction with the π-electrons of the double bond.

This work forms a part of a larger investigation which will be given in detail elsewhere.

Transformation of Frequency Distributions

FREQUENCY distributions of numbers of eggs, insects, spores, or other biological entities are descriptive of discrete variation, and can never be represented *exactly* by a normal distribution or by any other distribution of a continuous variate. Nevertheless, when the number of observations and the range of variation is large, such distributions may often be *adequately* represented by a continuous distribution. Experience has shown that transformation of discrete counts to a scale of $\sqrt{n}$, log n, or log $(n + 1)$ may considerably assist the representation by a normal distribution.

The device of plotting the cumulative distribution in probit units against a proposed square root or logarithmic scale of counts, as suggested by Gaddum[1], is useful as a rapid test of whether or not the right normalizing transformation has been found: if the distribution is effectively normal on the transformed scale, the probits will be linearly related to the counts. Spiller[2] has recently commented on this procedure. He has stated that statistical analysis in terms of this linear regression seems preferable to argument from the parent distribution, but that methods of calculating regressions and variance do not appear to be available.

In all uses of probit methods, however, the parent distribution must be kept in mind. The standard methods of calculation associated with probit analysis[3] have been devised for data in which the cumulative distribution is estimated directly from the observations, and they are clearly not appropriate here. The regression equation for a diagram such as that drawn by Spiller is, in fact, a line which attains a probit value of 5·0 at the mean value of the sample (on the transformed scale), and which has a slope equal to the reciprocal of the standard deviation of the sample; an application of statistical theory to the problem of estimating this line would show that the parameters of the line were to be obtained from that mean and standard deviation. As Gaddum has stated, "The best estimates of the mean and standard deviation will be obtained by applying the ordinary methods directly to the transformed observations".

Some idea of the values of the parameters may be formed by measurement of the diagram. For example, Spiller's line *B* has a value of about 0·70 for log $(n + 1)$ at a probit of 5·0, and an increase of unity in log $(n + 1)$ corresponds to a probit increase of about 1·9. Hence the distribution of log $(n + 1)$ may be regarded as approximately normal, with mean 0·70 and standard deviation 0·53 ($= 1/1{\cdot}9$); these compare with values, calculated from Spiller's table, of 0·774 for the mean and 0·487 for the standard deviation. The size of the standard deviation relative to the mean suggests that agreement with a normal distribution cannot be very close (though it may be good enough for comparisons between samples to be made with the aid of normal distribution theory), and comparison of the frequency polygon with the calculated distribution would confirm this. The probit diagram may indeed be deceptive for data of this kind, since considerable deviations from normality are not always apparent by inspection of it.

THE INTERNATIONAL ASTRONOMICAL UNION

AT the seventh General Assembly of the International Astronomical Union which was held at Zurich during the week beginning on August 11, more than three hundred astronomers from thirty countries met (in many cases for the first time for ten years) to discuss their past results, their current problems and their future plans. The machinery of international collaboration, kept going during the War by the good offices of astronomers in neutral countries, had been overhauled at a meeting of the Union's Executive Committee at Copenhagen in the spring of 1946; and it was largely because of the spadework put in by that committee, then and since, that the full Assembly could get on with its business so expeditiously at Zurich. The Federal Institute of Technology was kindly made available to delegates throughout the week. The hundred sessions held by the forty commissions into which the Union is subdivided put no severe tax on the accommodation available, and the many mixed commission meetings, colloquia and informal lectures, though they were well attended, could always find an auditorium of ample size. It was evident that behind the smooth functioning of the local arrangements, which included (as well as the formal business) a full programme of social events and sightseeing trips for delegates and their guests, lay a tremendous amount of hard work by a most efficient organising committee, headed by Prof. Waldmeier, director of the Zurich Observatory.

After an inaugural general assembly at which warm welcomes were accorded the delegates by the civic authorities and by the Swiss National Committee of Astronomy, and were responded to by the president of the Union, Sir Harold Spencer Jones, the members devoted a short session to administrative business. The financial load on the Union has been considerably eased by a decision of Unesco to support many bodies, such as the Bureau International de l'Heure and the International Latitude Service, the world-wide scope and general scientific value of which deserve such support. The Union in its turn eased the financial burden on its less wealthy adherent countries by altering the system of paying dues. Instead of paying, as now, on a *per capita* basis, countries will in future be classified (on their own proposal, ratified by the Executive Committee) into eight categories, each paying different subscriptions. By this modification countries with large populations, such as India or China, will be relieved of the necessity of paying dues out of proportion to the extent to which astronomy has developed within their borders.

The next five working days were devoted to purely scientific matters. Discussion varied, as always, from prepared contributions to a symposium attended, perhaps, by a hundred delegates, to fierce wrangles around a table on some obscure technical point between the only three people in the world aware of its import. At the commission meetings themselves, the business was partly organisational and partly scientific, the proportion varying with the subject-matter of the commission. At one end of the building a handful of delegates might be revising the code for astronomical telegrams or the list of standard astronomical notations, while at the other a no less earnest group would be discussing the constitution of interstellar matter, or the emission spectrum of the night sky.

In the commissions concerned with positional astronomy, modern methods for improving meridian work were discussed. The Russians have successfully experimented on photo-electric recording of transits of the brighter stars, while the Washington transit circle is now fitted with cameras which record all readings photographically so as to reduce fatigue in the observers and eliminate erroneous logging of the results. New instruments are being designed, some of them (notably those at Greenwich) based on new principles chosen so as to eliminate many of the most troublesome errors that beset meridian work. Photographic astrometry proceeds apace with wide-angle lenses and now with Schmidt cameras, and the application of punched-card methods to repetitive computation is being followed by the development of automatic plate-measuring devices which feed measured co-ordinates direct to the mechanical computers. Inconsistencies recently found in the adopted system of the fundamental astronomical constants are to be attacked by a research team in the United States, and authors are urged not to make *ad hoc* alterations pending the report of this team.

The solar commissions were faced with tremendous advances in our knowledge since the previous meeting, at Stockholm in 1938. Solar-terrestrial relationships, if little better understood, are now reduced to some sort of order since the importance of solar flares and active coronal regions became clear; the coronal spectrum is no longer a mystery, even if the corona still is; and on the instrumental side astronomers now have the help of prominence cinematography, the Lyot polarization filter, and the V2 rocket for exploring the sun's ultra-violet spectrum. But with these advances have come new problems; and much time was taken up in discussing solar radio noise, corpuscular emission from solar flares, and chromospheric structure. Nor have all the long-standing problems been cleared up, as was shown when two of the liveliest controversies of the week developed around the supposed variations in the solar constant and the magnitude of the sun's magnetic field. There was a powerful appeal for further direct observations to confirm the Smithsonian measurements of the solar constant when reports of indirect checks (via the brightness of the moon and of Uranus) revealed conflicting results. As for the sun's magnetic field, so much recent work has been based on the classical results at Mt. Wilson that there was something of a sensation when it was announced that both Mt. Wilson and Hamburg Observatories had recently failed to detect the field with apparatus that had apparently confirmed its presence only a year or two ago. Whether this failure is due to a real change in the magnitude of the field or to an under-estimate of the size of the accidental errors of observation did not emerge; but a suggestion that the matter might be settled by measuring the polarization of the sun's radio emission from its north or south hemisphere during an eclipse was seized on as a hopeful way out of the quandary.

In the field of research on nebulæ, observers and cosmologists met on common ground. Recent spectrophotometric work has shown that the more distant nebulæ are redder than can be accounted for by the red-shift in their spectra, that is, the colour indices of the nebulæ increase with distance. This is conceivably an evolutionary effect: for if, as is currently believed, the red supergiant stars in the nebulæ exhaust their internal store of nuclei available for energy generation more rapidly than other stars, the distant nebulæ, which we see in their youth, will indeed be redder than the older ones in our neighbourhood, from which the red giants have faded. But whatever the explanation, this reddening must seriously affect those nebular counts to limiting magnitudes on which depend our present observational tests of various world-models. An interesting but inconclusive discussion took place on whether the classification sequence of the external galaxies is also an evolutionary sequence; and if it is, whether the sense of evolution is not towards rather than away from the elliptical forms. The cosmologists present carried the observers with them in an appeal to present observational results in a form which would facilitate rather than preclude a comparison of the different theories of world structure; in particular, to refrain from applying dubious 'corrections' for cosmological effects which are based on a particular model and therefore exclude others from proper consideration.

In a crowded symposium on infra-red spectrophotometry, recent results obtained with photoconductive lead sulphide cells were presented. Perhaps the most spectacular are: the identification of the infra-red spectra of the Martian polar caps and of the rings of Saturn with reflexion spectra from hoar-frost deposited on solid carbon dioxide; the suggestion that the green areas on Mars are due not to vegetation but to lichens devoid of chlorophyll; and the discovery of methane high in the earth's atmosphere from telluric bands at 3·4 μ and 1·6 μ in the solar spectrum.

Other well-attended meetings considered the spectral sequence and its anomalies (perhaps the most important paper here was a Russian one showing that a variety of observational data could be explained if interstellar matter is concentrated into small discrete clouds about 10 parsecs in diameter), the outer layers of the sun, and current progress with the 200-in. telescope. It seems that after a little preliminary trouble with the mirror supports, all goes well with the latter. The figure is approaching perfection, which the opticians define as "correct to 1/10 wave", and the light-grasp is up to expectations.

Animated discussions took place when the commission on international observatories met. Sharp cleavages of opinion emerged on the relative value of the various proposals which had been made, all designed to show that astronomy at least can override political boundaries. It was finally decided to proceed with all the immediately practicable parts of the schemes, including plans for establishing an international telescope in the southern hemisphere, an international astronomical laboratory in Europe (including a library and optical shops and a computing centre), and an international travel fund for facilitating exchange of astronomers.

The meeting reached its climax with a conference on the cosmic abundances of the elements. Since the 1938 meeting a measure of agreement has been reached on the nuclear reactions controlling energy generation in the stars, and interest now centres on the allied problem of elemental abundances. As a result of the present conference, it is now clear that no significant differences of abundance exist between the sun, the main-sequence stars and even the planetary nebulæ and interstellar matter, and that the proportions of the elements found in the earth's crust and in meteorites differ from the cosmic proportions only in physically explicable ways. The high-luminosity stars, however, lie on a mass-luminosity curve appropriate to a much higher mean molecular weight than the sun's; and it seems likely that, as was expected from their high rate of radiation, these giants have already burned up a considerable part of their hydrogen content. While discrepancies do undoubtedly exist in certain celestial bodies, it would be fair to say that the observed abundances do fit present conceptions reasonably well. The next move is to explain how the present abundances arose, and some steps have already been taken in this direction.

At the concluding general assembly some general resolutions were passed, the lists of members and of commissions were revised and new officers were elected. The incoming president is Prof. B. Lindblad, of Stockholm; the new general secretary is Prof. B. Strömgren, of Copenhagen. No decision has yet been reached on whether to hold the next meeting, in 1951, at Leningrad or Pasadena. With a final vote of thanks to its Swiss hosts for making possible a most successful meeting, the seventh General Assembly of the Union was declared closed on August 18.

VITAMIN C IN POTATOES

By Dr. FRANK WOKES
Ovaltine Research Laboratories, King's Langley, Herts
AND
GORDON NUNN
Oakley Training College, Cheltenham, Glos.

THE vitamin C content of potatoes is known to diminish steadily during the autumn and winter, so that their contribution towards the national requirements of this vitamin is considerably diminished. The average content of vitamin C in *raw* potatoes, as found by different workers, has been summarized by Lampitt, Baker and Parkinson[1] and is indicated by the shaded area in Fig. 1. The

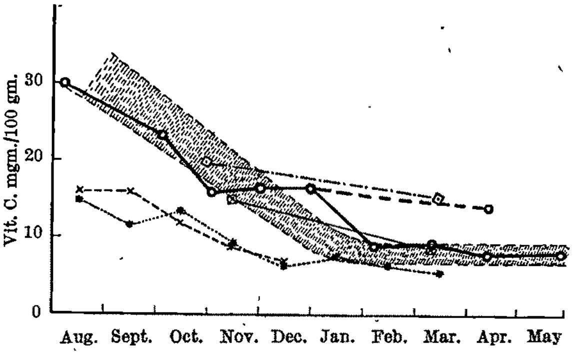

Fig. 1. Seasonal changes in vitamin C content of potatoes. The shaded portion represents average content in raw potatoes in different seasons as summarized by Lampitt, Baker and Parkinson. Results on raw potatoes stored in clamps indicated thus:

Results on cooked potatoes indicated thus:

Olliver (1943), ×– – – –×
Thompson (1944), •············•

vitamin C content of *cooked* potatoes, as found by different workers[2,3], is indicated in the same figure by dotted lines, and will be seen to be less than that of the raw potatoes but to show a similar decline in the latter part of the year. Certain workers[4] have found that in raw potatoes stored in clamps the vitamin C content does not always fall so steeply as would be expected from the average figures. No convincing evidence has been forthcoming to show that this was due to temperature changes. The question how to diminish, and if possible prevent, this loss of vitamin C is therefore not yet satisfactorily answered.

In the course of some storage experiments on potatoes which we have been carrying out recently, we have made some observations which may perhaps be of interest. The potatoes we used (Kerr's Pink) were grown in Cheltenham and stored in an experimental clamp, samples being withdrawn at regular intervals for testing. Results obtained on these potatoes are indicated in Fig. 1 and show that, after the usual drop in the autumn, the average vitamin C content became steady in three batches taken during November and December, but fell again in January, February and March. These results are based on duplicate assays on more than a hundred separate potatoes, enough being taken to ensure that the alterations in the slope of the curve at the end of October and at the end of December were highly significant.

When looking for a possible cause for the unexpected stability of the vitamin experienced by ourselves, and occasionally by other workers[4], we first considered the storage temperature. Daily records of the maximum and minimum temperature in the storage clamp did not provide the explanation we were seeking. Moreover, in some of our potatoes stored in the refrigerator we experienced a greater loss of vitamin than in others of the same variety of potatoes stored at higher temperatures (see table). Taken in conjunction with the findings of previous workers, who detected no difference in the rate of loss at different storage temperatures from 3° to 31° C., our results seem to show that storage temperature *per se* is not a decisive factor.

Effect of storage conditions on rate of loss of vitamin C in potatoes

Storage conditions	% Loss	No. of weeks	% Loss per week
Closed containers			
at 4–5° C.	14·1*	10	1·4
at 27° C.	20*	7	2·9
Open to air			
(L) at 30° C.	41	9	4·6
at 4–5° C.	75†	20	3·8
(L) at room temperature (20° C.) in dark	32	6	5·0
	26	9	2·9
(L) at 31° C. in dark	23·5	5	4·9
	23·5	9	2·6

This table includes results obtained by Lampitt and his colleagues (marked L).
*Indicates less significant (p = 0·1–0·2).
† Indicates highly significant (p = 0·01).

We next considered the effect of atmospheric moisture. Our potatoes, like those of Lampitt and his colleagues, also stored in the refrigerator and referred to in the table, were exposed to air and therefore to a higher relative humidity than the potatoes stored at higher temperatures. It seemed to us feasible that the absorption of moisture from a more humid atmosphere might increase the tendency to form sprouts and thus use up some of the vitamin C in the potato. Rainfall records for the area in which our experimental clamp was situated showed that there was, in fact, very little rain during the period November–December, when the vitamin C content of the potatoes remained constant, but much more rain in January and February, when the vitamin C content fell. As a further test of this hypothesis, we examined in April some of the potatoes which had been taken for seed purposes from the clamp at the beginning of January and since stored in a dry shed. The vitamin C content of these potatoes was significantly higher than in similar potatoes stored in the clamp during this period; for example, 13·9 ± 0·4 as compared with 7·7 ± 0·4 mgm./100 gm. When these seed potatoes were stored in the same humid atmosphere as the main stock for a few days, they began to sprout and their vitamin C content fell to 8·1 ± 0·9 mgm./100 gm. (the second figure given above is the standard deviation of the mean).

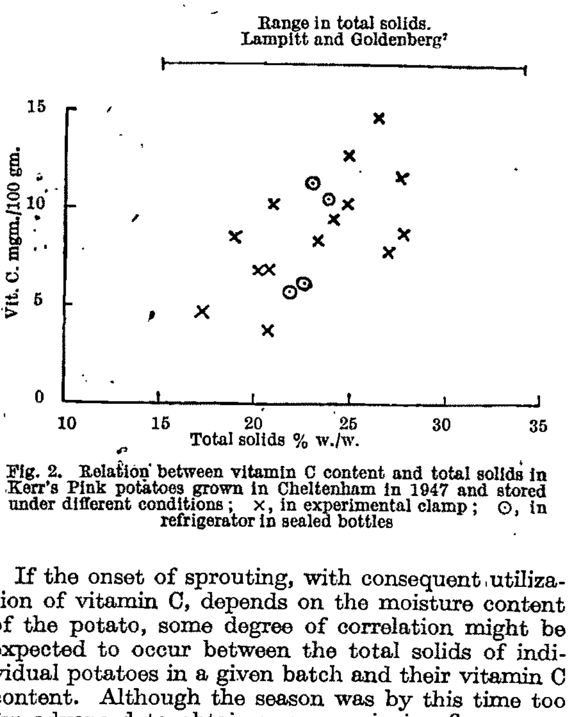

Fig. 2. Relation between vitamin C content and total solids in Kerr's Pink potatoes grown in Cheltenham in 1947 and stored under different conditions; ×, in experimental clamp; ⊙, in refrigerator in sealed bottles

If the onset of sprouting, with consequent utilization of vitamin C, depends on the moisture content of the potato, some degree of correlation might be expected to occur between the total solids of individual potatoes in a given batch and their vitamin C content. Although the season was by this time too far advanced to obtain very convincing figures, we attempted to investigate this question, and think that our data, summarized in Fig. 2, at least suggest the possibility of such a correlation. We hope that publication of these preliminary findings may stimulate other workers to study this problem, the solution of which should benefit the diet of the nation.

We are indebted to Misses Finnegan, Morphet and Raynor and to Mr. D. B. Kingston for assistance, and to Glaxo Laboratories, Ltd., for the loan of a Waring blender used in preparing some of the extracts.

ORIGIN OF LANGUAGE

By Prof. ALEXANDER JÓHANNESSON
University of Iceland

IN articles in *Nature*[1], I have set out the conclusion that a great part of human speech originated in the speaking organs' unconscious imitation of the gestures of the human body, especially the hands. The three articles dealt only with Ide. and Hebrew (as representative of the Semitic group). I have continued my researches and this time chosen the sounds *l* and *r*, which I have systematically investigated in Ide., Hebrew, Archaic Chinese, Polynesian, Sumerian and partially in Greenlandic.

	Ide.	Hebrew	Arch. Chin.	Polynes.	Sumerian
Examples with l:					
1. Sound	*lêu-* (Ags., *léop*, 'song')	*lw-n*, 'to mutter'	*liw-ər*, 'eulogy'	*leo*, 'the voice, speech'	*lu-ga*, 'to scold'
2. Light, colour	*leuq* (Lat., lux)	*lw-ḥ*, 'to shine'	*luk*, 'to look carefully' (*liuk*, 'green')	*roherohe*, 'a torch' (in P. *r* and *l* interchange)	*luǵ*, *laǵ*, 'light'.
3. Water	*leiqu-*, 'wet' (Lat., liquor)	*lḥ-ḥ*, 'be wet'	*lia*, 'thin wine'; *log*, 'rain water'	*rewa*, 'melt, become liquid'	*li-*, 'fat'; *lù*, 'muddle, disturb the water'.
4. To break, scratch, etc.	*lem*, 'to break' (Old-Bulg. *loml'ja*, 'to break')	*lm-d*, 'to stab'	*lâp*, 'to break'	*rami*, 'to squeeze'	*laǵ*, 'to strike'.
Examples with r:					
1. Sound	*rās-*, 'to sound' (Old-Ind. *rás-ati*, 'cries, sounds'	*rz-h*, 'to cry'	the hard '*r*' does not exist	*rāra*, 'to roar'.	
2. Light, colour	*reg*, 'to colour' (Gr., *ῥεζω*)	*rah*, 'to see'		*ra*, 'the sun'	*ra*, 'shining'.
3. Water	*reg-*, 'wet rain' (Lat., *rigare*)	*rh-t : rahat*, 'water-pipe'		*rire*, 'deep water'	*ri*, 'to flow'?
4. To break, scratch, etc.	*reis-*, 'damage' (Old-Ind. *riṣyati*, 'damages')	*rs̱-s̱*, 'to smash'		*raku*, 'to scratch'	*ri*, 'to throw down'.

In all these 'unrelated' languages the sounds *l* and *r* show a double origin: (1) that of a Nature sound (especially where *l* and *r* form the beginning of a syllable, or in the connexion vowel + *l* or *r*, but sometimes also in the combination consonant + vowel + *l* or *r*), and (2) that of a different (gestural) sound (mostly in the connexion consonant + vowel + *l* or *r*, but even vowel + *l* or *r*) as spontaneous imitations of the speaking organs to express the idea of the form or shape of things in Nature or to designate a movement.

The investigation shows that the most remarkable meanings of roots with the Nature sounds *l* and *r* (marked as l' and r' to distinguish them from l^2 and r^2, which mainly are a means of designating the shape or form or a movement, cf. above) are: (1) sound; (2) light, colour; (3) water; (4) to break, scratch, etc.

	Ide.	Hebrew	Arch. Chin.	Polynes.	Sumerian	Greenl.
Round, vaulted, curved, twisted, etc.	*k̂el-*, 'to enclose, cover' (Lat., color)	*kl-l*, 'to bend, encompass'	*kl-io*, 'round basket'	see under *r*	*gal* (*ga-al*) 'big'	*qal-eq*, '*ribbon*'
	k̂er-, 'string, to plait'	*kr-r*, 'be round, turn'	*k'iər*, 'bow down (the head) to the ground'	*kara*, 'an old man' (bent by age, cf. Gr. *γερων*)	*gar*, 'to encompass'; *gůr*, 'to bow'	*qar-ajak*, 'bay, encircled by rocks'
To move, to rise above, to grow, to lift, etc.	*tel-*, 'to lift' (Lat., *tollo*)	*dl-g*, 'to jump'	*lia*, 'depart from'; *tiər*, 'push away'	*tere*, 'to move swiftly'	*zal*, 'to extend' *sir*, 'be long, to remove'	
	reiq-, 'to arise' (Germ. *riegel*)	*rg-š*, 'turbulent movement'				

All these four subdivisions are closely related. It is an accepted theory that an impression on either the ear or the eye may give the same phonetical release (*Schall- und Lichtempfindung* in German handbooks)—presumably because they were originally symbolized by somewhat similar gestures. Thus Ide. *ghel*, 'to cry', and *ĝhel*, 'to shine', are related. No. 3 means water dripping, etc. No. 4, with the meaning 'to smash, to tear, to scratch', etc., shows that in those roots the *l* and *r* represent a hard sound (as also in some cases of Nos. 1 and 2).

More interesting is it to see how the 'unrelated' languages imitate the shape or form of things or movements. In the combination consonant + vowel + *l* or *r*, or vowel + *l* or *r*, we see how the idea of 'round, vaulted, curved, twisted', etc., or the idea of 'to rise above, to grow, to lift, to move', etc., came into existence by the speaking organs' spontaneous imitation of a curved form or movement.

The importance of comparing the roots in different languages may be seen by tabulating the number of Ide. and Hebrew roots with *r* according to their various meanings:

	No. in Ide.	No. in Hebrew
Sound	46	19
Colour	32	10
Water	19	14
To break, scratch	91	70
Round, vaulted, curved	103	26
To move, rise above	97	83
Total	388	222

To this may be added some other roots, especially with the meaning 'to cut' (Ide., 8 roots; Hebrew, 17) or 'to devour' or to be 'relaxed'.

As the roots with *l* have a similar extension to those with *r* we see that, in Ide. languages, the sounds *l* and *r* in the roots of approximately one word in three have more or less determined the meaning (the Ide. roots number 2200), and that in more than 50 per cent (200 out of 388 for the sound *r*) all words containing in the roots the sounds *l* or *r* are of gestural origin. This fact might encourage philologists to scrutinize systematically all combinations of sound-groups in the roots as the most important means of solving the problem how man learned to speak.

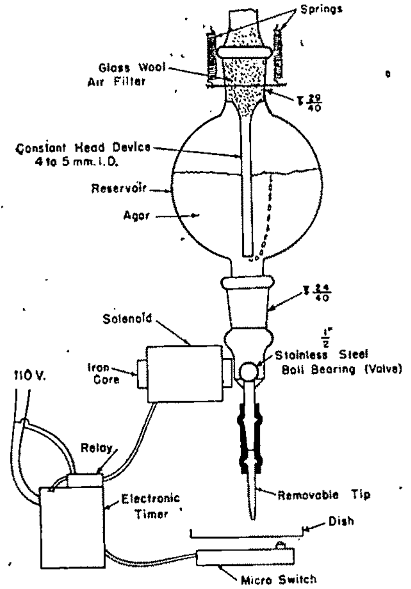
AN AUTOMATIC AGAR DISPENSER

By W. H. SCHMIDT[*], M. D. REEVES[†], FRANCIS J. CASTLE and R. G. BENEDICT

Fermentation Division, Northern Regional Research Laboratory[‡], Peoria, Ill.

IN many laboratories various types of semi-solid culture media are routinely dispensed in Petri dishes for use in the study of micro-organisms.

The automatic agar dispenser described in this article was originally designed for rapid and reasonably accurate transfer of melted agar to plates for subsequent use in the assay of penicillin. A notice of this was published some time ago[1]. Because of the interest shown in the apparatus by visitors from other laboratories, it appears desirable to publish a more complete description which will be more widely available. A drawing of the apparatus is reproduced herewith.



Assembly of agar dispenser

In principle, the device is simple. It consists of a constant-head reservoir which empties through a modified solenoid valve connected with an electronic timer. The only part of the apparatus considered difficult to make is the glass seat for the ball valve. This seat should be flattened so that no leakage can occur when the stainless steel ball is in its normal position. When the micro switch is pressed, the solenoid must not lift the ball but roll it to one side. Any timer, either mechanical or electronic, which makes or breaks a circuit may be used, the accuracy of the device depending upon the accuracy of the timer. The size of the glass reservoir for holding the agar depends on the quantities to be dispensed. For routine plate-pouring (20 ml. per plate), we use a vessel with a total capacity of 2 litres. For dispensing smaller amounts of agar, such as those required for flooding assay plates (4 ml. per plate), a 500-ml. receptacle is used. A delivery tip with a much smaller opening is attached to this vessel.

Sterilization of the reservoir and valve in our Laboratory is effected by passing steam in at the top and permitting it to escape to a drain by raising the ball valve with a straightened paper clip inserted through a small opening in the rubber tubing. The constant-head device and delivery tip are sterilized separately in an Arnold steamer. Autoclave sterilization may be substituted when steam is not available on the laboratory table. To guard against the possibility of pressure developing in the reservoir during steam sterilization on the table, two steel springs, attached at the top of the standard taper (29/40) male joint, are clipped to loops at each end of a wire ring, shown at the top of the reservoir. Should the ball valve accidentally close during sterilization, slight steam pressure pushes the top male joint up to prevent breakage of the reservoir. In assembling the apparatus, we close this top joint with only moderate pressure and do not employ any lubricant. The lower joint standard taper (24/40) connecting the bottom of the reservoir with the glass assembly containing the ball valve is greased with a temperature-resistant chemically inert lubricant.

Data on accuracy of delivery are shown in the accompanying table. A 2 per cent agar medium was melted and cooled to 48° C. before transfer to the glass reservoir. The timer was set to deliver 20 ml. agar (ball valve opened and closed in 1·5 sec.).

Accuracy of delivery of automatic agar dispenser
Weight in grams of 20 ml. samples, reading down from left to right

20·91*	20·60	20·54	20·40
20·80	20·72	20·65	20·32
21·08	20·62	20·28	20·27
20·76	20·32	20·74	20·30 (last sample)
20·64	20·71	20·41	
20·82	20·71	20·35	* First sample

Average weight of all samples delivered was 20·63 gm. Extreme variations from the mean value were +0·45 gm. and −0·36 gm.

One operator is able to handle thirty plates within 2–3 minutes. The dispenser is much simpler and faster than agar delivery by pipette, and more accurate than pouring plates from tubes containing measured amounts of the materials.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, December 6

FARMERS' CLUB (at the Royal Empire Society, Craven Street, Strand, London, W.C.2), at 2.30 p.m.—Dr. A. D. Buchanan-Smith: "Inheritance of Milking Capacity in Dairy Cattle".

UNIVERSITY OF LONDON (in the Department of Biochemistry, University College, Gower Street, London, W.C.1), at 4.45 p.m.—Dr. C. de Duve: "The Control of Carbohydrate Metabolism".*

(Further lectures on Thursday, December 9, and Monday, December 13.)

UNIVERSITY OF LONDON (at the Institute of Education, Malet Street, London, W.C.1), at 5.30 p.m.—Mr. K. L. Little: "Education for International Understanding—Africa".*

SOCIETY OF CHEMICAL INDUSTRY (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 6.30 p.m.—Mr. H. Seligman: "Application of Radio-active Elements in Industry".

ROYAL INSTITUTE OF CHEMISTRY (at Norwood Technical Institute, Knight's Hill, London, S.E.27), at 7 p.m.—Dr. A. Albert: "Drug Action, Ions and Neutral Molecules".

Tuesday, December 7

ASSOCIATION OF SPECIAL LIBRARIES AND INFORMATION BUREAUX, NORTHERN BRANCH (at the North of England Institute of Mining and Mechanical Engineers, Neville Hall, Westgate Road, Newcastle-upon-Tyne), at 10 a.m.—Conference on "The Value of Organised Information Service to Industry, Commerce and Education".

EUGENICS SOCIETY (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. J. W. B. Douglas: "Maternity in Britain—the Results of a Social Survey".*

Institution of Electrical Engineers (joint meeting of the Measurements and Supply Sections, at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Papers.

Society of Chemical Industry, Chemical Engineering Group (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Dr. E. F. Edson: "Radiation Hazards and their Control".

Sir Halley Stewart Trust Lecture (at the Memorial Hall, Farringdon Street, London, E.C.4), at 6 p.m.—Prof. D. W. Brogan: "The Atomic Age—America as Atlas".*

Wednesday, December 8

Physical Society, Colour Group (in the Large Physics Lecture Theatre, Imperial College of Science and Technology, Imperial Institute Road, London, S.W.7), at 3 p.m.—Scientific Papers.

Manchester Statistical Society (at the Reform Club, King Street, Manchester), at 5.30 p.m.—Air Vice-Marshal Donald Bennett: "Order in the British Air".

Illuminating Engineering Society (at Gas Industry House, 1 Grosvenor Place, London, S.W.1), at 6 p.m.—Reports and Discussion on the 1948 Meeting of the International Commission on Illumination.

Society of Instrument Technology, North-West Section (at the College of Technology, Manchester), at 7.30 p.m.—Mr. Longworth: "Functional and Performance Characteristics of Automatic Temperature Control".

Thursday, December 9

Physical Society (at the Laboratories of the Metropolitan-Vickers Electrical Co., Trafford Park, Manchester), at 9.45 a.m.—Scientific Papers.

Linnean Society of London (joint meeting with the Royal Entomological Society, at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Discussion on "The Bearing of the Parasite-Host Relationship in Taxonomy" (to be opened by Mr. G. H. E. Hopkins, Dr. J. Ramsbottom and Dr. O. W. Richards).

Royal Society of Medicine (at 1 Wimpole Street, London, W.1), at 5 p.m.—Discussion on "Colour Vision in Industry" (to be opened by Prof. W. J. B. Riddell, Prof. H. Hartridge, F.R.S., Dr. W. D. Wright and Dr. Leslie Norman).

Chemical Society (joint meeting with the Local Sections of the Royal Institute of Chemistry and the Society of Chemical Industry, in the Chemistry Lecture Theatre, The University, Manchester), at 6.30 p.m.—Prof. C. K. Ingold, F.R.S.: "Aromatic Nitration".

Textile Institute, Midlands Section (joint meeting with the Coventry Textile Institute, at St. George's Hall, Nuneaton), at 6.45 p.m.—Mr. A. Y. Stirrat: "Increasing Production in the Textile Industry by Training and Production Study".

Royal Photographic Society, Scientific and Technical Group (at 16 Princes Gate, London, S.W.7), at 7 p.m.—Dr. R. H. Herz: "The Action of X-Rays and Electrons on the Photographic Emulsion".

Society of Chemical Industry, Fine Chemicals Group (joint meeting with the Agriculture Group, at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 7 p.m.—Dr. W. A. Sexton: "The Chemistry of Plant Growth Regulators".

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 7.15 p.m.—Scientific Papers.

Society of Chemical Industry, Microbiological Panel of the Food Group (joint meeting with the Nottingham Section of the S.C.I., at the Nottingham Gas Show Rooms, Nottingham), at 7.15 p.m.—Mr. F. C. Bawden: "Some Properties of Plant Viruses".

Chemical Society, Edinburgh Section (joint meeting with the Local Sections of the Royal Institute of Chemistry and the Society of Chemical Industry, in the North British Station Hotel, Edinburgh), at 7.30 p.m.—Dr. D. W. Kent-Jones: "Bread and its Influence on History".

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Prof. G. Crowden: "A Survey of Physiological Studies of Mental and Physical Work in Hot and Humid Environments".

Friday, December 10

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Scientific Papers.

Institution of Mechanical Engineers, Applied Mechanics Group (at Storey's Gate, St. James's Park, London, S.W.1), at 6 p.m.—General Review of "Fluid Flow through Granular Beds" (Discussion based on papers by Dr. H. E. Rose and Dr. A. M. A. Rizk).

North-East Coast Institution of Engineers and Shipbuilders (at the Literary and Philosophical Society, Newcastle-upon-Tyne), at 6.15 p.m.—Dr. T. W. F. Brown: "British Marine Gas Turbines" (Parsons Memorial Lecture).

Institute of Physics, Manchester and District Branch (in the New Physics Theatre, The University, Manchester), at 7 p.m.—Brigadier R. A. Bagnold, F.R.S.: "Model Scale Experiments on Waves and Beaches".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. E. K. Rideal, F.R.S.: "The Emission of Light in Chemical Reactions".

Saturday, December 11

British Psychological Society (in the Hastings Hall, Tavistock House, Tavistock Square, London, W.C.1), at 2.30 p.m.—Prof. G. Humphrey: "Some Problems in the Modern Theory of Learning".

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 2.30 p.m.—Mr. Percy Edwards: "British Wild Birds and their Voices" (Pictures and Voices).*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Senior Lecturer in Physics at the Ministry of Supply School of Electronics—The Chief Superintendent, Telecommunications Research Establishment, Great Malvern, Worcs., quoting 5/138/JFA (December 11).

Lecturer (Grade IIc) in Chemistry—The Secretary, The University, Edmund Street, Birmingham 3 (December 11).

Deputy Laboratory Steward for the Department of Organic Chemistry—The Registrar, The University, Liverpool (December 11).

Electronic Physicists and Electronic Engineers (in the Senior Scientific Officer, Scientific Officer, Experimental Officer and Assistant Experimental Officer grades) in Ministry of Supply research and development establishments mainly in Hampshire, Worcestershire and Kent—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.161/48A (December 11).

Laboratory Steward to take charge of the maintenance of Physics and Chemistry Laboratories—The Warden, Goldsmiths' College, New Cross, London, S.E.14 (December 11).

Senior Scientific Officers, Scientific Officers, Experimental Officers, Assistant Experimental Officers and Scientific Assistants in the Air Ministry Soil Testing Laboratory under the Directorate General of Works in London or the Provinces—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting G.487/48 (December 13).

Deputy Survey Officer at the Coal Survey Laboratory, Cardiff—The National Coal Board, Establishment (General) Branch, Hobart House, Grosvenor Place, London, S.W.1, quoting TT/103 (December 13).

Teacher of Chemistry for matriculation and intermediate science classes—The Principal, Norwood Technical College, Knight's Hill, London, S.E.27 (December 13).

Assistant Lecturer in Philosophy—The Registrar, The University, Leeds 2 (December 13).

Assistant Warden for duty at Juniper Hall Field Centre, near Dorking—The Director, Council for the Promotion of Field Studies, 10 Exhibition Road, London, S.W.7 (December 14).

Crombie-Ross Chair of Mental Health—The Secretary, The University, Aberdeen (December 15).

Lecturer in Mechanical Engineering, a Lecturer in Civil Engineering, a Lecturer in Electrical Engineering, and a Lecturer in Automobile Engineering, at the Technical Institute, Yaba, near Lagos—The Director of Recruitment, Colonial Service, Sanctuary Buildings, Great Smith Street, London, S.W.1 (December 18).

Candidates for two posts in the Directorate of Scientific Control to carry out operational research—The National Coal Board, Establishment (General) Branch, Hobart House, Grosvenor Place, London, S.W.1, quoting TT/110 (December 20).

Deputy City Bacteriologist—The Town Clerk, Municipal Buildings, Dale Street, Liverpool 2, endorsed 'Deputy City Bacteriologist' (December 20).

Keeper of Art, a Keeper of Antiquities, a Keeper of Geology, a Schools Service Organiser, and an Assistant Keeper of Art—The Director, Museum and Art Gallery, New Walk, Leicester (December 29).

Chemists, Chemical Engineers and Fuel Technologists at the Dominion Laboratory, Wellington—The High Commissioner for New Zealand, 415 Strand, London, W.C.2 (December 30).

Candidates (Experimental Officer and Assistant Experimental Officer grades) for indexing and abstracting literature and official reports and supplying research workers with information—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.381/48A (December 30).

Professor of Botany—The Secretary and Registrar, University College of North Wales, Bangor (December 31).

New Zealand Research Fellowship—Research Applications British Federation of University Women, 17a King's Road, London, S.W.3 (January 1).

Economic Botanist in the Department of Agriculture, Fiji—The Director-General of Recruitment, Colonial Office, Sanctuary Buildings, London, S.W.1.

Candidate with a special interest in and general knowledge of the Rhynchota to undertake determinations and possibly later a certain amount of systematic revisionary work in that order of insects—The Director, Commonwealth Institute of Entomology, 41 Queen's Gate, London, S.W.7.

Departmental Demonstrator in Physical Anthropology—The Professor, Department of Human Anatomy, The University, Oxford.

Lecturer in Horticulture at the Kent Farm Institute, Sittingbourne—The County Education Officer, Springfield, Maidstone.

Assistant Manager (Production), a Technical Records Officer, and a Works Engineer (Maintenance), in the Department of Atomic Energy at Windscale Works, Sellafield, Cumberland—The Staff Section, Ministry of Supply, Department of Atomic Energy Risley, Warrington, Lancs.

Abstractors (male and female)—The Secretary, British Shipbuilding Research Association, 5 Chesterfield Gardens, London, W.1.

Experienced Metallurgist for the application of research results to industrial practice—The Secretary, British Non-Ferrous Metals Research Association, 81–91 Euston Street, London, N.W.1.

Technician (Grade II) in the Department of Civil Engineering—The Secretary, University College, Gower Street, London, W.C.1, quoting 'Civil Engineering/1'.

Visiting Demonstrator in Bacteriology—The Secretary, King's College of Household and Social Science, Campden Hill Road, London, W.8.

Meteorologist for Directorate of Civil Aviation, Government of Iraq—The Crown Agents for the Colonies, 4 Millbank, London S.W.1, quoting M.N.22047/3E.

SOCIAL AND ECONOMIC RESEARCH IN GREAT BRITAIN

IN considering the provision made for research in Great Britain into social and economic questions, the Clapham Committee, reporting in July 1946, was satisfied that unless the existing arrangements and plans were upset in some future economy campaign, the provision for such research within the government machine was much more likely to be hampered by the lack of properly trained staff than by failure to realize the importance of the work to be done. Developments in the departments and in the central secretariat promised well for the future of research in this field. It was, however, highly desirable that the Government departments which collect and analyse material relevant to social and economic research should be in continuous contact with outside experts, who could keep them aware of the needs arising in the speculative branches of the field and who could assist in assessing the value and possible uses of material which is already being collected. Equally it was desirable that there should be continuous contact between the relevant divisions within the different departments, both to avoid overlapping and to ensure that the potential value for research purposes of the material available was exploited from every point of view.

The Clapham Committee accordingly recommended the establishment of an interdepartmental committee charged with the duty of bringing to the notice of departments the potential value for research purposes of the material which they collect, and suggesting new methods and areas of collection. The appointment of such a standing committee was announced by the Chancellor of the Exchequer on January 21, 1947, and in its first report now issued*, the Committee examines the availability, for academic research, of statistical data and other descriptive matter available in Government departments. Much of this material is already known to and used by academic research workers, and the departments themselves benefit considerably from the fundamental research or studies in methodology proceeding at the universities. The interdependence of the departments and the universities in the field of the social sciences is now clearly recognized.

The Interdepartmental Committee recognizes the value of the close personal contacts established during the War, when many members of university staffs were employed in Government departments, and it is convinced that there is no adequate substitute for them. Such contacts should not only be maintained but also multiplied; and the Committee regards it as one of its principal functions to stimulate all forms of collaboration, whether formal or informal, between the departments and research institutions. Personal contacts in themselves are not enough; but while the Committee's recommendation remains designed to supplement, not to supersede, the direct contacts now existing between individuals, it is not likely to sponsor expensive schemes which aim at theoretical completeness as regards the covering of information, rather than what is economically worth while in view of the effects of such personal contacts. The Committee acknowledges the assistance given in this part of its work by the memorandum submitted by the National Institute of Economic and Social Research as a result of the conference on research relations with Government departments, to which reference was made in some detail in the last annual report of that Institute (see *Nature*, July 31, 1948, p. 197).

---

* Report of the Interdepartmental Committee on Social and Economic Research. (Cmd. 7537.) Pp. 16. (London: H.M. Stationery Office, 1948.) 4*d.* net.

Before tackling the wider and more general questions confronting it, however, the Committee thought it advisable to ensure so far as possible that any new schemes which departments might be projecting for collecting and tabulating social and economic material should at the outset make reasonable provision for research needs. Information obtained about the number and condition of the people, their health, their work and their needs is obviously capable of much fuller use when it is so handled at the outset that it can serve more than immediate administrative requirements. From the point of view of the individual citizen, quite apart from that of economy, there are obvious advantages in such co-operation; and it is encouraging to learn that not only is there wide interest in the work of the Committee and a general willingness to co-operate, but also that three of the major departments of State, the Ministry of Agriculture and Fisheries, the Ministry of Education and the Board of Trade have already asked for guidance on particular tabulation schemes.

In studying the material which Government departments collect and publish, the Committee decided to work in the first instance through sub-committees making a close study of one department or group of departments, and strengthened as needed by co-opting additional academic or other members with special knowledge of the particular field. In these surveys, the immediate objects are to find out what information is collected, the extent to which this information could be made available, and whether there are any fields of statistical or other information in which a change in present methods of collection or treatment might benefit departmental or other research workers. These surveys began with the Ministry of Labour and National Service, Prof. R. G. D. Allen being co-opted to the sub-committee concerned. A guide to the material available through this Ministry has already been published, but the sub-committee's report also led to a recommendation to the Ministry that some of the unpublished information already in the possession of the Ministry, such as information about working days lost through industrial disputes, wages and juvenile employment, should be assembled and published. Other information, it was suggested, should be published in greater detail or more frequently.

Man-power considerations may well preclude action on some of these recommendations at the present time; although if like recommendations emerge as the outcome of the work of the sub-committee at present studying the work of the Board of Trade, it might well be possible to implement them by transference and not by the engagement of further staff. Investigations along these lines should assist the research worker to find out what material is available in the departments, and it should be noted that the Committee considers that the publication of the Guide of Current Official Statistics should be resumed at the earliest possible date and not delayed for the incorporation of references to unpublished material which is also available.

Location, however, is only one aspect of the subject. The research worker also wants to be certain that the material he requires will not be destroyed before he can consult it. One of the main functions of the Public Records Office is to ensure that research material is not destroyed, and as the pamphlet on "The National Register of Archives", published in 1945, shows, the services of the Office to social and economic research in the preservation of documents are not limited to material in the possession of Government departments. The Committee, while appreciating the importance of the work of the Public Records Office in this field, suggests that it has been regarded too exclusively as a source of information about the past; certain proposals are accordingly made with the view of enabling the Record Office to offer a more positive contribution to those engaged in contemporary research. One such proposal, that the words "or useful for social and economic research" should be added to the paragraph inserted in every schedule governing the disposal of departmental records to ensure that they are examined by a competent officer before they are destroyed, has already been accepted.

The Interdepartmental Committee further proposes that the Public Record Office should issue a publication classifying all the documents preserved either at the Public Record Office itself or elsewhere under its jurisdiction. It suggests further that more might be done in framing the schedules which govern the preservation and destruction of records to make them more immediately intelligible to research workers. Attention is also directed to the special case of war-time collections of data in departments, and to the risk that these may not be sufficiently used for research purposes.

The scope of the Committee was limited to research work in Government departments, but it does not overlook the importance to social and economic research generally of avoiding the dispersal, loss or destruction of the records of industries now nationalized or being nationalized. This matter lies outside the terms of reference of the Committee, and is related to the question of the preservation of business records generally. Nevertheless, the Committee has brought the matter to the notice of the Office of the Lord President of the Council, and this report should do much to help the work of the British Records Association in this field. The suggestions in this report could find considerable application to business records also, as will be apparent to any reader of the paper by Dr. Chaloner on "Business Records as a Source of Economic History", read before the Northern Branch of Aslib last autumn and now available in the *Journal of Documentation*. That paper was specially concerned with the selective preservation of business records in libraries. Here the principles laid down by the Interdepartmental Committee regarding the confidential character of Government information have a close bearing, and some at least could be applied. If it is a recognized duty of Government departments towards the society of which they are the institutional agents to make available, at least for the purposes of scientific inquiry, as much as possible of the information which they possess, business firms can scarcely disclaim all such responsibility. Indeed, although much that passes for the history of particular firms or industries scarcely meets the criteria of R. E. Collingwood in "The Idea of History", at least the volume of such monographs is considerable enough to indicate that industry recognizes a responsibility of this character. In the opinion of the Committee, a *prima facie* case exists for publishing, or making otherwise accessible, all information of general social utility, unless there is good reason to the contrary; and such *obiter dicta* cannot well be limited to Government departments.

Whether this be universally applied or not, it is necessary to be clear as to what constitutes a good reason to the contrary. Government departments have first to observe faithfully statutory requirements, though opportunities might well be taken, in amending legislation, to modify obsolete requirements. The requirements of security and public policy have also to be met, in the Departments of State and in business or industry, though liberal interpretation of rules may well be called for; and in Government departments and in industry practical administration must not be hampered. Likewise, it is reasonable to insist that the cost of making the information available should not be out of proportion to the importance of the subject-matter; and whatever the source of the information, public interest demands that the obligation, whether statutory or otherwise, ensuring that individual persons, firms and other entities are not publicly identifiable, must be discharged.

That there will be some difficulties is not denied; but the Committee points out that such difficulties have been surmounted even in fields in which access to information of a personal or individual nature is essential. The general observance of such a code of rules in respect not only of information available in Government departments or commercial firms, but also information obtained by the departments for administrative purposes from trade unions, employers' federations and trade and professional associations, and the scheduling of such documents on similar lines might immensely enrich the field of research available for accredited research workers. It is a necessary and reasonable corollary to any such proposals that all persons concerned exercise particular care that the material is only used by such workers.

Besides the confidential material, there is much non-confidential information, particularly of a statistical nature, which could be made available for social and economic research. Copies of such unpublished documents might well be distributed to specialized libraries where outside research workers might consult them. The Committee, in fact, compiled such a list, including university libraries, research libraries within the universities and the libraries of other research bodies of standing and of learned societies. A number of departments have already indicated their willingness to co-operate, and the intention is to ascertain by experiment the documents which such libraries wish to receive, and then to see if regular distribution could be arranged.

The emphasis on this report is on finding ways in which the Departments of State could assist the outside research worker more effectively than they do now. There is the complementary question, which may well increase in importance, of the help which research workers can incidentally give the Departments of State. There are always academic research projects in progress which bear at least indirectly on Government problems, and in this connexion the Committee refers to the value of the Register of Research in the Social Sciences compiled by the National Institute of Social and Economic Research. The need is primarily for collaboration between the Departments of State and research workers; and this first report warrants the belief that the Standing Committee will provide a powerful stimulus to such co-operation, and even to the use for social and economic research of the much larger amount of material available in business records.

FORCES INSIDE THE ATOMIC NUCLEUS

Nuclear Forces

By Prof. L. Rosenfeld. (Monographs on Theoretical and Applied Physics, Vol. 1.) Pp. xix+181. (Amsterdam: North-Holland Publishing Co., 1948.) £1 4*s.* 5*d.*

THERE is a mass of experimental material in nuclear physics, much of which gives information about the forces acting between nuclear particles. The theory of nuclear forces, on the other hand, is still inadequate. Even the law of force between two nucleons is unknown, though meson theory suggests a form, but leaves numerous parameters to be settled by comparison with experiment. The research literature of nuclear physics is consequently chaotic, and the appearance of a book on the subject is to be welcomed. In his preface, Prof. L. Rosenfeld explains the reasons which led him to adopt a discursive approach to his subject at the expense of brevity and at the risk of losing the basically simple thread of the argument. The result has been a book which is not easy to read quickly by anybody who wants to discover the central ideas of the subject. The wealth of detail, which might well have been relegated to appendixes, will prove very valuable to research workers in the field, particularly to those entering it for the first time, but may well try the patience of the more general reader trying to learn something of this important branch of physics.

Only volume 1 has so far appeared, and it is a pity that a list of references and a provisional subject index could not have been prepared for it. The text abounds with references to a bibliography at the end of the book; but the reader who turns to the end of the present volume will find a disappointing blank. This is all the more unfortunate in connexion with the table of nuclear data and figures summarizing them, which are referred to in the text. It is to be hoped that the remaining volumes will soon become available, so that the student who wishes to read the original papers may know where to find them, and be able to consult what must be a very useful compilation of data.

The present volume, after an introductory survey of the whole field (Part 1), is confined to detailed consideration of two-nucleon systems, on the hypothesis that only central forces are effective. The first chapter of Part 1 deals with the elementary particles of physics and their properties. How difficult a task it is to write a book about a rapidly developing subject is demonstrated by the absence of any reference to the recent discovery by the Bristol physicists that there are at least two kinds of mesons in the cosmic rays, and that the mesons which occur at sea-level are not those which play a part in the nuclear forces. This discovery, though scarcely a year old, has called for revision of our ideas on the subject, which could not be included in this volume. The remainder of Part 1 is devoted to considerations of the simpler properties of nuclei, such as their binding energies, radii, etc., and the arguments pointing to the saturation property of nuclear forces.

In Part 2, one chapter is devoted to general considerations on the wave equations of the two-nucleon system, two chapters to detailed considerations of the proton–neutron system (that is, the deuteron and the scattering of neutrons by protons), one chapter to the proton–proton system and a final chapter to a comparison of the forces between like and unlike nucleons. These topics are treated with an encyclopædic thoroughness which will certainly make the book a standard work of reference for many years to come.

The book, though written in English, is printed in Holland. The printing is attractive and pleasantly free from misprints; but the formulæ are disfigured by symbols in strange types and a luxuriant growth of prefixes, affixes and suffixes. These latter also disfigure the text by having made it impossible for the printer to keep an even spacing between the lines; they could well have been omitted without loss of clarity. M. H. L. PRYCE

A SOUTH AMERICAN ANTHROPOLOGICAL SYMPOSIUM

Handbook of South American Indians

Edited by Julian H. Steward. (Smithsonian Institution: Bureau of American Ethnology, Bulletin 143.) Vol. 3: The Tropical Forest Tribes. Pp. xxvi+986 +126 plates. Vol. 4: The Circum-Caribbean Tribes. Pp. xx+609+98 plates. (Washington, D.C.: Government Printing Office, 1948.) n.p.

THE first two volumes of this work, dealing with the marginal tribes and the Andean civilizations, were introduced in *Nature*, Nov. 30, 1946, p. 769. Those now under review cover vast areas in eastern and northern South America, besides the West Indies and most of Central America south of Mexico. These regions were more sparsely covered by published information even than those dealt with in the first two volumes, so their preparation has involved a great deal of research, one result of which was to show that the arrangement of sub-areas planned for vol. 3 was largely artificial, though it was too late to alter it, and that much of the information on Colombia in vol. 2 might more properly have been included in vol. 4. The editor points out that the fragmentary nature of the information about many of the tribes treated in vol. 3 has resulted in prolixity rather than in brevity, since it has forced authors to let original accounts speak for themselves, retaining much detail which may be unimportant, and has prevented them from making reliable summaries of the basic features. This is not to say that these volumes are less valuable than their predecessors or any less necessary to students of South American archæology and ethnology; in fact, they represent, if anything, a greater advance on our previous knowledge about the areas they deal with.

In vol. 3 the emphasis is, naturally, on the modern Indians rather than on the archæology, about which there is little to say, although parts of eastern Bolivia and the Napo region of Ecuador, about which at least a little is known, seem to have escaped mention both here and in vol. 2. The Indians described are mainly in their original state, unlike those in the Andes in that they are little affected by culture contact. As a matter of convenience, the tribes of northern Colombia and of Venezuela north of the Orinoco are dealt with in vol. 4.

A general principle of great interest and importance, which is indicated by the survey of this area, is that the tropical forest type of culture spread upstream from a centre in the lower Amazon and the Guianas as far as its limit at the edge of the Andean zone, and it is considered that there was little cultural diffusion overland either from the Orinoco basin or the Andes. It is further suggested that the tropical forest culture came originally from the circum-Caribbean area, and the argument is carried further in vol. 4, where the idea of a circum-Caribbean culture, whence the forest culture is derived by degeneration, is developed. It is shown that, at the time of the conquest by the Spaniards, a number of tribes in that area had an elaborate culture, now vanished, which probably resembled that of the Formative Period in Mexico and the Andes, with a strong bias towards the latter. This implies that cultural flow in Central America was mainly from the south. Opportunity is taken to point out the weakness of the theories of origin of American civilizations which ascribe them to the areas least known at the time of enunciation, and to show how inherently improbable is the idea that the essentials of the higher civilizations could have come from the forests.

In contrast to vol. 3, there is a good deal to say in vol. 4 about archæology, and there are extremely useful summaries dealing with the Central American countries, Venezuela and the West Indies, by acknowledged experts such as Strong, Lothrop, Alfred Kidder II and Rouse. There is a large amount of information about the modern tribes, in spite of the fact that many of them are relatively degenerate survivals, as has already been implied. The area dealt with includes northern Colombia, but it is rather unexpected to find the Cayapa and Colorado of western Ecuador in this volume.

The extent of our debt to the Bureau of American Ethnology for this vast undertaking gradually becomes apparent as publication advances. In order that we may get the best out of it, an index is urgently needed, and it is to be hoped that one is planned for the final volume. G. H. S. BUSHNELL

TECHNICAL WRITING

The Presentation of Technical Information

Based on four Public Lectures given at University College, London. By Prof. Reginald O. Kapp. Pp. xi+147. (London: Constable and Co., Ltd., 1948.) 6*s.* net.

SINCE the lectures on which this book is based were delivered in April and May of 1947, the publication of Sir Ernest Gowers' "Plain Words" has stolen some of Prof. Kapp's thunder. There is some common ground in the two books, but Prof. Kapp is concerned with the presentation of technical information and deals with the choice and use of words only so far as they contribute to that purpose: whether or not technical terms, words are to be chosen deliberately so as to serve the technical ideal of fitness for the purpose. That is the ideal which is in Prof. Kapp's mind throughout, just as it dominated Prof. J. R. Nelson's "Writing the Technical Report", a second edition of which appeared last year. Prof. Kapp insists that the presentation of technical information demands the use of what he terms functional English—language in which words are chosen and sentences constructed so as to express the writer's meaning clearly and without ambiguity, and are as appropriate to his purpose as the units selected and used by the designer of an engineering construction. Functional English, he claims, presents facts and ideas simply and logically, but jargon is eschewed by him as firmly as by Sir Ernest Gowers or by Quiller-Couch in a lecture that few scientific writers appear to have discovered.

In his 150 pages, Prof. Kapp includes much that should help the technical or scientific writer to select the words most appropriate for his paper, report or book, and which will best assist the reader—or hearer, for Prof. Kapp is concerned with spoken as well as written exposition—to understand his meaning. Primarily, it is the postgraduate student to whom the book is addressed, but it should be equally welcomed by other students at an earlier stage, though Prof. Kapp provides no ready-made guide or model to be copied. The book is a challenge to real thinking about the task of presentation.

The expositor's first task before he even begins to select his material is to be quite clear in his own mind as to the purpose for which the information to be supplied is required and the reader or audience for whom it is intended. Unless we know the exact purpose to be served we cannot choose the appropriate tools for the task. No commoner error is made, however, in presentation than neglect to decide on that purpose or on the reader to be addressed. By apposite examples, Prof. Kapp illustrates a number of simple rules, observance of which will enable the scientific man to present the results of his investigations in much more readable and therefore effective form. Moreover, Prof. Kapp does this, too, by stimulating thought as well as by pertinent comments on prevalent use and abuse of words, and his book is admirably designed to meet a need voiced at the Royal Society Scientific Information Conference as well as in an ever-growing volume of books and papers.

Prof. Kapp's own book is original in its approach, and his treatment of the theme is clear, vigorous and searching. The book may justly be preferred to some of its more voluminous predecessors, but its merits can scarcely justify the virtual ignoring of all other publications on the subject; and some of his readers might well be grateful for references to other books or papers in which they could pursue their study of a subject Prof. Kapp illuminates but scarcely exhausts. He refers, indeed, but vaguely to a paper on the subject in the *Journal of the Institution of Electrical Engineers* since published by that Institution with others under the title "The Presentation of Engineering Evidence", and apart from the considerable number of books, some indeed of unequal value, concerned with the writing of reports or scientific papers, he gives his readers no indication of the existence of useful and entertaining literature on the handling of words themselves whether for technical or general purposes. R. BRIGHTMAN

INDEX KEWENSIS

Index Kewensis Plantarum Phanerogamarum

Supplementum Decimum: Nomina et Synonyma Omnium Generum et Specierum ab initio Anni 1936 usque ad finem Anni 1940 nonnulla etiam antea edita complectens. Ductu et consilio A. W. Hill (obiit 1941) et E. J. Salisbury. Pp. iii+251. (Oxford: Clarendon Press; London: Oxford University Press, 1947.) 84*s.* net.

FROM the time of its original appearance in 1893, the "Index Kewensis" has been one of the monumental works in the literature of systematic botany, and the publication of Supplements at regular intervals has always marked a notable stage in the records of plant taxonomy. The appearance of the tenth Supplement is no exception, and although on this occasion there has been inevitable delay in its production, it will none the less receive a warm welcome from botanists throughout the world. To the authorities at Kew every botanical institute must feel indebted for the continuation of an indispensable work of reference.

The present volume covers the five-year period 1936–40, and in its general plan it is similar to previous Supplements. Each page carries three columns, and generic names are arranged alphabetically, as also the specific names under each genus. Some idea of the immense amount of work involved in the preparation of an index of this kind may be obtained from the fact that each of its 251 pages deals with about 105 specific names. This gives an indication also of the contribution which has been made to the systematic study of Phanerogams in the period under review. Not only have large numbers of new species been described, but also numerous new genera have been established, notably in the families Cactaceæ, Compositæ, Gramineæ, and Rubiaceæ. The delimitation of genera in these and other families not infrequently presents considerable difficulty, and it is not surprising that some of the new generic names which appear in the Supplement are due to the elevation of previously recognized sub-genera.

As would be expected, the species which have been described as new to science are distributed among many genera; but the additions to certain of them, such as *Carex*, *Hieracium*, *Peperomia*, *Piper*, *Rubus*, *Quercus* and *Salix*, are conspicuous by their number. The pages of the Supplement as a whole, however, are testimony to the amount of systematic work which was achieved before the War brought botanical exploration temporarily to a standstill, and they give evidence of the substantial contribution which has been made to our knowledge of the world flora. Such an authoritative list of the names of plants, giving the author and place of publication of each, together with reference to synonymy and geographical distribution, is indispensable to all workers on the taxonomy of flowering plants.

An additional feature which distinguishes this from earlier Supplements is the insertion of an asterisk against those entries where an illustration accompanies the description of the new species. In this simple way the "Index Kewensis" will continue the function of the "Index Londonensis", a work which was brought to a conclusion in 1941.

J. R. MATTHEWS

ENCYCLOPÆDIA OF EYES

Tabulæ Biologicæ

Vol. 22: Oculus, Pars 1. Editores: K. Steindorff, F. P. Fischer, J. S. Friedenwald, Arnold Sorsby. Pp. viii + 408. (Amsterdam: Dr. W. Junk, 1947.) 70 fl.

ONE of the functions of science is to collect information and to classify it. Some of the information so collected may appear to any one person to be trivial or of little importance, but let that person remember that he is not the only oyster in the bed, and he will realize that the sand grains around him may become pearls for others. To one interested in the activities of the human eye there may seem to be little significance in measurements which relate the width of the ocellus of an ant to the breadth of its head; but to another, interested in the behaviour of ants, this information may be of far more value than statistics on the occurrence of blondes in Austria, or the relation between intra-ocular pressure and the thymus gland. The first part of "Oculus" contains collected numerical data on the structure and anatomy of eyes of all types, on the behaviour of the pupil and on vascular pressures in the eye; and the reader will find a wide diversity of subject-matter, including such topics as those mentioned above. The net is cast wide and the information collected is vast and various. Three further parts of the book are to follow, so that almost every aspect of the eye will be dealt with, each by a different author.

The task of collecting the data and preparing it for publication was largely undertaken or inspired by the late Kurt Steindorff, who clearly saw the advantages to be gained by collecting together as much information as possible in order to assist in elucidating the mysteries of vision. He might be described as the oculomotor nucleus.

In such a subject as vision, upon which the relevant literature is immense and still rapidly growing, it is easy to be critical on the grounds that such and such a table is not included in this volume; but since most of us who work on vision have experienced the mixed thrill and disappointment of finding that our much cherished ideas were either suggested or carried out in the last century, such criticism necessarily loses much of its force. Nevertheless, on such matters as the structure and distribution of the retinal constituents it is disappointing, for example, to find no references to the data collected by Polyak or Osterberg. There has clearly been some inevitable delay in the publication of the volume, and thus many of the more recently derived data are not included. Moreover, the index is to appear in a later volume and the bibliographies are arranged numerically, more or less in order of appearance in the text, and not alphabetically according to authors, so that it is difficult to be certain that one does not miss information through searching for it in the wrong place. Such difficulties will, of course, vanish when the whole work is published, and, when this occurs, ophthalmologists of all types will have an extremely valuable compendium of information.

E. N. WILLMER

VEGETABLE GROWING

Vegetable Growing

By Prof. James Sheldon Shoemaker. Pp. v+506. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1947.) 27s. net.

IT is unusual to find a North American book on any aspect of practical horticulture which is of much direct value in Great Britain. Prof. J. S. Shoemaker, perhaps because he is primarily a man of science, has produced a book which is an exception to the rule. The reason lies in the method of approach to the subject, which is more through the requirements of the crop than its detailed culture. While it is true that much of the discussion on varieties has little application in Britain, yet, because of the closer horticultural links of Canada with the home country, many more English varieties are included than one would find in a book from the United States.

Because of the prime importance of good seed in successful vegetable cultivation, the book starts with a discussion on seed production. This is undoubtedly a most valuable section, since few books on vegetables give more than cursory attention to the subject. The major part of the work is devoted to the specific crops, grouped according to use; for example, corn crops, root crops, salad crops, etc. The traditional procedure of giving preliminary chapters on soils, fertilizers and other considerations has been abandoned in favour of discussing these problems in relation to each crop, thus enabling direct application of research findings to be presented in their proper context. It is this treatment which lifts the book out of the general run of gardening manuals and raises it to scientific levels.

A surprising omission, however, in a book of this high standard is that of scientific names and botanical characteristics. The history of each vegetable is most admirably summarized, but to the serious student the interest and value would be greatly enhanced by reference to the botany of the crop. This is particularly true of the last chapter, on insect and disease control. Of what value to a student, especially in another country, is a reference to "early blight" and "late blight" of celery unless he knows that these are due to two different fungi, *Cercospora apii* and *Septoria apii*? Again, what is one to understand by "haywire", "calico" and "jelly-end rot" of potatoes? Even where the genus of an insect or a fungus is mentioned or clearly obvious, addition of the specific name would avoid confusion with other species possibly more common in another country. Perhaps in a second edition the author will bear in mind the needs of workers and students in Britain and elsewhere.

R. H. STOUGHTON

Cours de mécanique

Par Henri Beghin. Tome 1. Chapitres 1 à 3. Pp. ix+102. Chapitres 4 à 7. Pp. 103–201. Chapitres 8 à 11. Pp. 202–367. Chapitres 12 à 14. Pp. 368–488. Chapitres 15 à 18. Pp. 489–588+9. (Paris: Gauthier-Villars, 1948.) 1,800 francs.

IN order to avoid the current delays of printing, M. H. Beghin's book has been manifolded from typescript, a process which does not make for elegance; but the merits of the work are not thereby obscured. Based on lectures given at the École Polytechnique, the first volume deals with kinematics, with elementary statics, and with dynamics of a particle and of simple rigid bodies, going as far as Lagrange's, Appell's and Hamilton's equations. Vector methods are used when appropriate, but are not overdone.

A preface by General Brisac, commandant of the École Polytechnique, claims three points of M. Beghin's work for special praise—its simple presentation of principles, its systematic exposition of mechanics as an experimental science, and its sense of concreteness. The book shares with most other French treatises on rational mechanics a clear and logical view of dynamical principles and a power of simple yet precise exposition. But the contact with reality is a marked feature, and here M. Beghin's account is akin to the best of British text-books; and he is not above including some exercises for the student, though these are often of the type which we in Great Britain should expect to see as worked examples to illustrate the text. Fortunately, he despises the monotony of "A uniform rod of mass *m* and length 2*a*", and the majority of his examples are genuinely instructive. The long Chapter 7, "Exercices simples de mécanique terrestre", is full of good sound matter, clearly expressed, and of definite practical importance. Granted the French recognition of the value of pure science to the Fighting Services, it is easy to believe that M. Beghin's courses at the École Polytechnique were greatly appreciated.

The second volume is to deal with gyroscopic motion and with the mechanics of fluids and of elastic solids.

The Electrolytic Capacitor

By Alexander M. Georgiev. Pp. xii+191. (New York and Toronto: Murray Hill Books, Inc.; London: Crosby Lockwood and Son, Ltd., 1945.) 15*s*. net.

IN this age of electronics, we have ceased to marvel at the sight of incredibly complicated circuits being packed into ever smaller and smaller boxes. Few probably pause to consider the great part that has been played by the development of the electrolytic condenser in order to achieve these feats of space compression.

In Mr. A. M. Georgiev's book, all the aspects of electrolytic capacitors are considered, and running right throughout the book there is the comparison of the 'wet' with the 'dry' type of electrolytic condenser. The main theme is of a commercial and engineering nature, and a good deal of space has been devoted not only to the manufacturing processes but also to the details of the electrical equipment necessary for testing and fault-finding. On the other hand, the more academic aspect has not been overlooked, and a whole chapter (5) has been devoted to an outline of the many and various theories and hypotheses that have been advanced in an attempt to explain this curious dielectric surface of an aluminium anode, which is the starting-point of the whole subject.

There is much information to be obtained from this book, and in addition there is a very extensive bibliography, index, list of relevant patents and glossary (in which many of the terms are quite elementary). As such, this volume will be of much interest not only to qualified chemical engineers, but also to the scientific layman who is interested in the actual manufacture or use of electrolytic condensers.

Introduction to Wireless

By W. E. Pearce. Pp. viii + 247. (London: G. Bell and Sons, Ltd., 1948.) 7*s*. 6*d*. net.

THIS book is likely to appeal to the layman who is anxious to know something about how his wireless set works, and who may be expected to have forgotten all he ever knew about elementary electricity and magnetism. This may justify the inclusion of the material in Chapters 2–7. From Chapter 8 onwards the author does deal with radio; but the book is not strictly an "Introduction to Wireless" in the sense that it might form a suitable first-course text-book for serious students. The ground covered is too wide and the treatment too general and not sufficiently rigorous.

As a book for the general reader not concerned with becoming an expert, the book is well written and apparently free from very serious errors, although in places there is some confusion of thought, as on p. 99, for example, where the analogies between potential and kinetic energy on one hand and the energy in the electric and magnetic fields on the other seem to have become slightly mixed.

The author would have been better not to invite the reader to doubt his (the author's) capabilities by describing certain phenomena as "difficult to explain".

The book is well produced, and the text and diagrams are clear and readable. W. R.

Bird Haunts in Northern Britain

By G. K. Yeates. Pp. 175 + 119 plates. (London: Faber and Faber, Ltd., 1948.) 25*s*. net.

THERE is a special fascination and charm about the birds of the northern parts of the British Isles. The very names, 'whimbrel', 'black-throated diver', 'greenshank', and so on, seem to have a peculiar appeal. In this account of his experiences on the mainland of Scotland and in Shetland, Capt. Yeates conveys this fascination to the reader. He writes of birds and bird matters in a pleasant and informative manner, illustrating his text with many photographs. Bird photographers to-day are legion, and they vary much in skill; but Capt. Yeates is among the leaders in this branch of the photographer's art, and the 115 reproductions in black and white are good examples of his work, all being excellent, and many fine. In addition there are two reproductions in colour from 'Kodachrome' originals and two plates from paintings by Mr. G. E. Lodge. Colour photographs and paintings do not always bear comparison, the work of the brush generally winning from the artistic point of view; but in this case all the pictures are admirable, the 'Kodachrome' reproductions being accurate in colour rendering and at the same time soft and harmonious. As for Mr. George Lodge's pictures, it suffices to say that they are what we have long learnt to expect from this skilled painter of birds, fine colour effects being combined with great accuracy of plumage detail.

FRANCES PITT

GENETICS IN THE SOVIET UNION

By Prof. ERIC ASHBY
University of Manchester

SINCE last August there have been reports in the Press of a crisis among biologists in the U.S.S.R. The crisis culminated in a decree from the Præsidium of the Academy of Sciences, published on August 27. This decree dismisses a number of prominent biologists from their posts, closes two famous laboratories, and removes orthodox geneticists from committees and editorial boards of the Academy. The Press reports have not been complete or objective; and the only full accounts of the crisis have been in the Russian language. British biologists will be grateful, therefore, to the Commonwealth Bureau of Plant Breeding and Genetics, which has now brought out a summary[1] of the conference which led to the crisis, from articles in *Pravda* over the first three weeks of August. At the same time, an English version of Lysenko's speech at this conference has been published under the auspices of the Society for Cultural Relations with the Soviet Union[2]. These two documents, together with an essay published by the Bureau of Plant Breeding two years ago[3], and an illustrated account of Lysenko's experiments[4], provide the British reader with adequate data to interpret the recent decree of the Academy of Science.

The Lenin Academy of Agricultural Sciences, of which body Lysenko has been president for ten years, held a Conference during July 31–August 7 of this year. It was reported that several new members had been elected to the Academy, all 'Michurin-biologists'; Lysenko delivered a presidential address of some nineteen thousand words; and there was a long discussion in which many members took part. After Lysenko had spoken it was revealed that his address had been previously examined and approved by the Central Committee of the Communist Party.

Lysenko's address[2] follows familiar lines. It contains a re-statement of the antithesis between so-called Mendelism–Morganism and the new Soviet genetics based on Michurin. It denies the chromosome theory of heredity. It arraigns several Soviet biologists because their work is inconsistent with Marxist ideology and is sterile of practical results: M. M. Zavadovsky, because he admires Morgan; I. I. Schmalhausen, because his theory of stabilizing selection is "profoundly wrong ideologically" and has "a disarming effect upon practical activity"; A. R. Zhebrak, because his work on wheat polyploids has "produced literally nothing of practical value"; N. P. Dubinin, because the work on population genetics (upon the strength of which Dubinin was elected a corresponding member of the Academy of Sciences in 1947) is of no practical importance; and so on. Lysenko complains that the work of his school has been suppressed by the Academy, the Ministry of Agriculture, and the Ministry for Higher Education. He attacks the universities for using as their genetics text a book by the Americans Sinnott and Dunn. He explains that Michurin biologists will no longer be in a minority in the Agricultural Academy, "thanks to the interest taken in it by the Party, the Government, and Comrade Stalin personally". He then proceeds to give an outline (the clearest yet published in English) of his methods of "shattering" heredity by graft-hybridization and by partial vernalization. The mainstay of his evidence is still the experiments of Avakyan and Yastreb[5], which were discredited in 1944. The objective of Lysenko's attack on Mendelism is not so much its false ideology, but rather its impotence. By insisting on the stability of the germ plasm Mendelism "condemns practical workers to fruitless waiting". The inheritance of acquired characters is a doctrine necessary for the progress of Soviet agriculture.

Lysenko's speech was followed by a discussion which has been ably summarized by the Commonwealth Bureau[1], and which makes fascinating reading. There is a chorus of testimony to the efficacy of Lysenko's methods, a renewed insistence on utility as the test of a scientific theory, and a condemnation of Mendelian geneticists in the U.S.S.R., mainly on the grounds that they are wasting time. Dubinin's work, for example, is described by Yakuskin as a monstrous deviation from the tasks of a Soviet scientist, and by Mitin as "unpatriotic". The State Seed Committee is criticized for insisting that new varieties should be homozygous. The Academy is criticized because its three biological journals have refused to accept papers on Michurin biology, and the University is criticized for turning down some doctors' theses on Michurin biology.

These contributions to the discussion make it abundantly clear that before last August biologists in the U.S.S.R. were free to work and publish and teach orthodox genetics, and that the Academy of Sciences, and the Ministries of Agriculture and Higher Education, were putting some of their weight, at any rate, on the side of Mendel and Morgan. Nor, even last August, had the orthodox geneticists been silenced. Nemchinov, Zhebrak, Rapoport, Alikanyhan, Zhukovsky, Schmalhausen, all defended their views against Lysenko's attack, though some of them made declarations of a change of their views at the end of the session. Clearly there is now, for the first time, a 'party line' on questions of biology in the Soviet Union.

About three weeks after this Conference the Academy of Sciences of the U.S.S.R. met, and adopted the new party line on biology. As a consequence of this, the Biological Section of the Academy has had to be reorganised, and this is the purpose of the decree of August 26, which is translated in full by the Commonwealth Bureau of Plant Breeding and Genetics. The effect of the decree is to bring to a stop many lines of work which had earned the admiration of biologists all over the world: Dubinin's studies on population genetics; Schmalhausen's work on natural selection; the work of Zhebrak on colchicine-induced wheat polyploids, of Sacharov on buckwheat polyploids, of Navashin on chromosome structure; and the splendid genetics course built up by Serebrovsky in the University of Moscow, with its thorough training in biometry, will have to be scrapped. Michurin-genetics, which has hitherto been up against a 'non-co-operation policy' from the leaders of biology in the U.S.S.R., now has a clear field.

Many biologists outside the U.S.S.R. will react with indignation to these events; for science as a whole' is the poorer by the elimination of these admirable schools of genetical research in the U.S.S.R. Earlier crises in Soviet science have been so inadequately reported that it was difficult to form a sound judgment as to what had happened. On this occasion we have a good record of the facts.

PARBOILING TREATMENT OF RICE

By Dr. J. J. C. HINTON

Research Association of British Flour-Millers,
Cereal Research Station, St. Albans

THE pre-milling treatment of paddy known as parboiling, involving treatment of the unhulled rice with hot water and steam, is established commercial practice, and for some time considerable attention has been paid to this and similar methods which aim at improving the nutritive value of rice; these latter include 'conversion' processes in which the steam is applied under pressure, sometimes preceded by a stage when the paddy is held under partial vacuum. Reviews of the subject have been prepared by the Economic Advisory Council, London[1], and the U.S. National Research Council, Washington[2]. These treatments result in a higher content of water-soluble nutritional factors, particularly those of the B group of vitamins, in the milled rice. It has been generally accepted that this is due to a redistribution of the nutrients within the grain, so that the endosperm is considerably enriched.

The distribution of vitamin B_1 within the rice grain is very similar to its distribution in wheat[3], and 45–50 per cent is found in the scutellum[4]. Furthermore, Nicholls has recently observed that, in contrast to untreated rice, in most samples of parboiled and converted rice the scutellum portion of the germ appears to remain in the grain after milling, and he has suggested that the explanation of the effect of pre-treatment may be found in this fact rather than in the re-distribution of nutrients[5]. The present article describes some experiments bearing on this interesting suggestion.

Parboiling and the Distribution of Vitamin B_1

Vitamin B_1 is readily assayed and may be taken as an index of the behaviour of the other soluble nutrients. An examination of the vitamin B_1 distribution was carried out on grain freshly treated on a laboratory scale. A conversion method of treatment, known as the Malek process, was used, small samples of paddy being heated in water at 75° C. for 4 hours, roughly dried on a cloth, and steamed at a pressure of 15 lb. per sq. in. for 15 min. 15–20 grains were dissected by first removing the embryo and scutellum. The end of the grain was then cut off, and the pericarp, aleurone layer and endosperm removed from the centre portion of the grain. The outermost layer, amounting to 15–20 per cent of the endosperm, is described as endosperm 1, and the remainder as endosperm 2. The vitamin B_1 content of these portions was determined by the microthiochrome method[6] and expressed on an air-dry basis of approximately 12 per cent water content. The results of several experiments are given in Table 1.

Table 1. Vitamin B_1 content (I.U. per gram) of parts of the rice grain untreated and converted by a parboiling process

Sample	Embryo	Scutellum	Pericarp-aleurone layer	Endosperm 1	Endosperm 2
1. Untreated grain	23	63	10·5	0·45	0·10
2. 4 hr. after parboiling	5·9	0·4	0·5	0·56	0·32
3. 4 hr. after parboiling			0·6	0·54	0·44
4. 72 hr. after parboiling	nil	nil	2·3	0·73	0·44
5. 12 days after parboiling	nil	nil	0·9	0·40	0·10
6. 4 hr. after parboiling	21·4	11·2	3·6	0·88	0·22
7. Heated to 75° C. for 4 hr., not steamed	24·4	30·7	6·2	0·80	0·20
8. 12 hr. after parboiling	3·2	2·1	0·65		
9. 23 days after parboiling	5·3	2·8	0·77		
10. 23 days after parboiling	6·4	3·8	0·71		

Excepting sample 5, all the samples show redistribution of vitamin B_1 in varying degree; the endosperm, particularly the outer endosperm, is enriched while the normally rich parts of the grain are impoverished. An analysis of the endosperm immediately in contact with the scutellum was also carried out, and the results are given in Table 2.

Table 2. Vitamin B_1 content of germ and adjoining endosperm in raw and parboiled rice

	Germ (scutellum and embryo)		Endosperm	
	Weight (mgm.)	B_1 (I.U. per gm.)	Weight (mgm.)	B_1 (I.U. per gm.)
1. Untreated	8·7	44	13·5	0·44
2. Parboiled	6·3	9·5	12·3	5·2
3. Parboiled	5·7	8·7	15·8	4·6

The figures reveal appreciable movement of the vitamin B_1 from the germ into the endosperm in the parboiled samples.

There are well-marked differences in the results of the tests shown in Table 1. Thus in numbers 4 and 5, no vitamin B_1 remains in the embryo or scutellum, and though there has been some re-distribution in 4, there is a total loss of about 75 per cent of the vitamin B_1, while there was no re-distribution in 5 and a total loss of 89 per cent. These samples were dissected some time after being treated; but the loss is not due solely to this storage period, as is shown by 9 and 10, which are sub-samples of 8 dissected 23 days later. Again, in sample 6, there has been little reduction in vitamin B_1 in the embryo and about 20 per cent of the original remains in the scutellum. Samples 2, 3, 8, 9 and 10 are between these two extremes of behaviour.

These differences were investigated further by examining the behaviour of dissected germ under the conditions of treatment of the paddy, and the conclusion was reached that they were probably due to the presence of a variable amount of water of condensation during the steaming stage. On the other hand, it seems likely that the presence of some free water during steaming is essential for effective re-distribution. The data obtained by examining the dissected germ portions (obtained from a sample of rice different from that of Table 1) are shown in Table 3 and will be discussed with those in Table 1.

Table 3. Vitamin B_1 in dissected rice germ subjected to various treatments

Sample of germ	Embryo (I.U. per gm.)	Scutellum (I.U. per gm.)
Control	31	45
1. Steamed in plugged tube. (Largely out of contact with steam)	21 20	20 21
2. Steamed on filter paper	16 13	20 21
3. Steamed on watch glass	1·5	2·0
Liquid in watch glass equivalent to	13·0	24·0

For the steaming treatment in the samples described in Table 1, small samples, 5–10 gm., of paddy were spread out on a clock-glass, filter-paper or an open beaker. When a clock-glass or beaker was used, considerable water of condensation was present; in tests 4 and 5 the grain swelled and burst, while in addition some liquid water remained on the clock glass in test 5. Samples 2, 3, 8 and 9 were spread on filter paper which would absorb most of the water of condensation; in these samples much less grain-swelling occurred and there was only slight opening of the hulls. It thus seems that heavy loss of vitamin B_1 from the germ is coincident with the presence of an excessive amount of water of condensation. The behaviour of the dissected germ in Table 3 supports this conclusion; steamed on filter paper, there is a reduction of about 50 per cent; steamed on a watch-glass, there is a reduction of about 95 per cent, but about 45 per cent was recovered from the condensate on the watch-glass, leaving an overall loss of about 50 per cent as before, which is probably due to thermal destruction of vitamin B_1.

Sample 6 of Table 1 was steamed in a flask plugged with cotton-wool; steam would reach the inside more slowly and condensation on and around the grain might be completely prevented. There was no obvious swelling and opening of the hulls, and the paddy was scarcely altered in appearance. There is very much greater retention of vitamin B_1 in the germ, the embryo showing almost its original value; while at the same time the re-distribution is less than 3 and 4, shown most markedly in the inner endosperm. The behaviour of the dissected germ (Table 3, sample 1) is broadly in agreement with this, the difference in behaviour of scutellum and embryo, however, being less marked.

In sample 7 steaming was omitted, and the vitamin B_1 is re-distributed to about the same degree as it is in 6, suggesting that the temperature of the steaming treatment alone has no effect on re-distribution.

These results suggest that re-distribution is determined mainly by the entry into the grain, as the starch gelatinizes, of a small amount of water condensed on its surface. The effect of the preliminary air exhaustion in, for example, one patented process known as the H.R. Conversion Process, may be to introduce water between the hull and the grain in addition to, or instead of, water of condensation. A great excess of water such as was present in some of the experimental tests led to almost total loss of vitamin B_1, while in the absence of sufficient water effective distribution did not take place.

It is to be noted that in these experiments the scutellum was more sensitive to the steaming treatment than the embryo, and that a considerable proportion of the vitamin B_1 of the germ and aleurone layer was not re-distributed but lost, at any rate as measured by the thiochrome method. In sample 4, about 75 per cent of the total vitamin B_1 was lost, and in samples 2, 6 and 9 about 50 per cent. Figures in the literature for rice prepared in a commercial conversion plant indicate a loss of about 20 per cent.

Parboiling and the Retention of Germ

(*a*) The residual germ, which was mainly scutellum, was dissected from the samples shown in Table 4 and the vitamin B_1 determined in the germ and grain. These samples had been parboiled and milled on normal commercial machines to produce the usual form of polished rice. The age of the four samples was unknown.

Table 4. Germ and vitamin B_1 contents of samples of milled rice

	Grain	Germ		
Sample	Vitamin B_1 content (I.U. per gm.)	Vitamin B_1 content (I.U. per gm.)	Proportion of the grain by weight	Percentage of total B_1 of grain
Parboiled No. 1	0·40	1·0	0·4 per cent	1·17
,, ,, 2	0·60	0·9	0·45 ,,	0·67
,, ,, 3	0·65	0·84	0·34 ,,	0·44
Raw	0·20	22·0	0·07 ,,	7·7

The three parboiled samples have a higher vitamin B_1 content and a much higher germ content than the raw sample. The B_1 content of the germ of the parboiled sample, however, is very low and contributes only about 1 per cent of the total vitamin B_1 of the grain. On the other hand, the small amount of germ left in the raw sample has a much greater vitamin B_1 content and contributes much more to the vitamin content of the grain.

(*b*) A second series consisting of samples taken at various stages of milling was examined. The treated samples had been prepared by a conversion process, and all the samples had been milled by normal commercial methods. There was very little difference between the vitamin B_1 content of the milled converted rice and milled raw rice, and the full data are therefore not presented in Table 5.

Table 5. Germ content and vitamin B_1 content of converted and raw rice

	Raw	Converted
Germ content of the milled rice	0·1 per cent	0·08 per cent
Per cent of grains containing some germ	6·0 ,,	90·0 ,,
Average germ content of grains which contain germ	1·71 ,,	0·09 ,,
	Vitamin B_1 content (I.U. per gm.)	
Hulled rice	1·38 per cent	0·48 per cent
Milled rice	0·43 ,,	0·49 ,,

The vitamin B_1 content of the milled raw rice is rather high, but is within the range reported in the literature; the B_1 content of the converted rice is low. No direct determinations were made on the germ; but the low vitamin B_1 content of the germ of the converted sample can be inferred from the low figure found for the converted hulled rice. The germ content in each of the milled samples is very low, the converted sample being lower than the raw sample. There is, however, an important point brought out in the figures. Only 6 per cent of the raw grains contained any germ, and those that did had an average germ content of 1·71 per cent. 90 per cent of the converted grains contained some germ, though the average germ content of each grain was only 0·09 per cent. Thus the germ content of the raw sample as a whole is due to a few grains which have completely missed the action of the milling machine, and contain almost the entire germ, while the great majority of the converted grains retain some germ, but this is much reduced in amount by heavy milling.

Another sample of converted rice from the same mill showed similar characteristics. 100 per cent of the grain contained some germ, but the germ content of the sample was only 0·05 per cent. Each of these samples appeared to have been heavily milled.

The suggestion that parboiling causes germ retention in milled rice is strongly supported by these results. A close examination of raw and freshly parboiled rice gives the reason. In cereal grains the scutellum is separated from the endosperm by a membrane formed by the walls of a layer of empty and crushed cells. In the rice samples so far examined, unlike wheat, for example, the endosperm in close contact with this membrane is loose and powdery, providing very poor adhesion. Normally, the skin layers and aleurone layer seal and hold the germ in the grain. The process of milling quickly removes the outer layers and the germ is then very readily dislodged; and this is what occurs in the samples of raw rice, the germ being lost not by rubbing down but by being knocked cleanly out of the grain.

Parboiling partially gelatinizes the endosperm, the powdery nature of the part in contact with the membrane is changed and adhesion is now extremely good so that the germ is not readily knocked out. There is also a slight toughening action on the germ itself, but this is not sufficient to prevent considerable loss if the grain is heavily milled.

Discussion and Conclusions

The large-scale processing of rice is not yet carried out in Great Britain. For this reason samples freshly prepared by commercial methods and otherwise of known history were not available for this work. Nevertheless, the experiments confirm that a parboiling or conversion treatment does lead to a re-distribution of vitamin B_1 in the grain, with the result that the endosperm is considerably enriched. Furthermore, there is an indication (sample 7 in Table 1) that simple steeping in hot water alone results in a measure of enrichment of the endosperm with vitamin B_1. However, it seems very probable that the maximum re-distribution is dependent upon water condensing, or being otherwise present, on the surface of the grain and entering into the gelatinizing endosperm. Under these conditions, vitamin B_1 is more or less rapidly lost from the germ.

The experiments also confirm the suggestion by Nicholls that there is a marked retention of the scutellum in milled parboiled rice as compared with milled raw rice, due largely to gelatinization of the endosperm immediately beneath the germ, which acts as a cementing layer so that the germ is not so readily knocked out or dislodged during the subsequent milling. It is not yet clear, however, how far this retention of germ is responsible for the higher vitamin B_1 content of rice milled after a parboiling treatment. This will depend upon the conditions of the treatment, that is, probably the amount of free water associated with the grain when gelatinization occurs. This in turn will largely determine the amount of vitamin B_1 retained in the germ. The fact, however, that the germ is not so readily dislodged from such grain does indicate the need for experiment on how far the type or severity of the milling process and the detailed conditions of pretreatment influence the quality of the final product. Clearly a high content of germ is desirable, apart from considerations of vitamin B_1 alone.

It would be of interest, for example, to study the effects of mild soaking in hot water (as in sample 7, Table 1) followed by light milling as an alternative to a boiling or steaming treatment followed by heavier milling, since this soaking had improved the adhesion of the germ by partially gelatinizing the endosperm beneath without seriously reducing its vitamin B_1 content.

I am indebted to Dr. Lucius Nicholls and Dr. C. W. Herd for the samples of rice.

THE FIGURE OF THE EARTH*

By PROF. HAROLD JEFFREYS, F.R.S.

ANY departure of the earth's external gravitational field from symmetry affects several geophysical and astronomical phenomena, especially observed gravity, the form of the level surfaces, which are normal to the direction of gravity, and perturbations of the moon, of which two are secular and one has a period of a month. There is a formal theory connecting them, which amounts to saying that if Ψ is the geopotential, defined by

$$\Psi = U + \tfrac{1}{2}\omega^2 r^2 \cos^2\varphi',$$

where U is the gravitation potential, ω the rate of rotation, r the distance from the centre of mass, and φ' the geocentric latitude, then Ψ is a constant C over the ocean surface, and gravity is the inward normal component of the gradient of Ψ. If the ocean covered the whole surface, observations of gravity over it would suffice to determine its form and the complete external field. The problem is different from those in potential theory, where we are told the form of a surface and either the potential or its normal gradient over it, and we have to find the other. Here we are told a lot about both the potential and the normal gradient, and have to find the form of the surface. The problem was solved to the first order by Stokes and to the second by Helmert.

The chief complication, of course, is that Ψ is not constant over the outer surface; but this was dealt with by Stokes. The point is that if h is the measured height, $\Psi = C - gh + O(h^2)$; and the observations thus refer to a surface where Ψ is known (apart from an additive constant) but is not constant. But if we form $g_1 = g(1 + 2h/a)$ and take gravity equal to g_1

---

* Substance of a paper at a Geophysical Discussion on October 22.

over a surface $\Psi = C$, the solution is practically identical with the correct one at points outside the earth and therefore gives the external field correctly. This is the free-air reduction. It plays such a fundamental part that we may say outright that there is no other way of allowing for variations of height above sea-level if we are to get the external field right. We cannot remove the effects of elevated matter on the field, and any process such as isostatic reduction that attempts to do so is simply a way of introducing systematic error.

When we try to use free-air values there is a difficulty, because in irregular country they vary irregularly and show a strong positive correlation with height. To represent a region properly, we want the mean free-air gravity over it, and therefore an estimate for the mean height of the region. Thus we have to take $g_1 = \alpha + \beta h$, find α, β by least squares, and use the solution to find $\alpha + \beta\bar{h}$, where $\bar{h}$ is the mean height of the region (*not* that of the stations, which have a way of being in valleys). I maintain that this is the only way of presenting gravity summaries that does not introduce systematic error or give a spurious appearance of accuracy. β is not the same in all regions; and over the ocean h must be replaced by the depth, and the solution must be adapted to mean depth. A reason often given for using isostatic anomalies* is that they are more regular than the free-air ones; but in most regions they are not appreciably more regular than the free-air ones with allowance for height, and the exceptions are precisely those where there is most risk of systematic error in using them.

When this method was applied to gravity, it was found convenient to classify the observations over 10° squares and get a mean value for the free-air anomaly for each. The means were found to show considerable irregularity, decidedly more than the apparent uncertainties will explain. Consequently it is useless to try to treat values for, say, 1° squares as subject to independent errors—there is a strong correlation of residuals at stations up to 10° apart and an appreciable one up to 30°. I speak of these as the τ_1 and τ_2 variations. Over and above the apparent uncertainty based on the departures for 1° squares from the mean, the 30° squares show a variation representable by a standard error τ_2 of about 15 mgal., and the 10° ones show one, with reference to the 30° means, of $\tau_1 = 21$ mgal. These should be right to about 2 mgal., and must be considered established. The values show no correspondence with mean heights of the squares, whereas any form of isostasy suggested would leave a positive correlation. The 'added mass' theory is, of course, worse; but we have reached a stage where further progress requires analysis of the residuals, and the isostatic theory gives us no help in understanding them. Isostasy must be regarded as a rough approximation for special regions where irregularity of height is extreme, and not even for all of them.

Even between adjacent 30° squares there is some correlation of the residuals. This could be due in part to errors of comparison of base stations. Assuming it genuine, I found four spherical harmonics in gravity of degrees two and three with longitude factors, and apparently significant amplitudes, besides small corrections to the mean and the main ellipticity term, but I should not like to be sure of them because some of the distant comparisons are under suspicion. The 10° and 30° variations, however, depend chiefly on comparisons with one base station common to each square and should be little affected by such errors.

The measurement of the radius and ellipticity of the earth by geodesy is essentially a matter of comparing the variations of latitude or longitude along an arc of measured length. As direction is measured by means of the plumb line, any irregularity of direction of gravity will be thrown into the latitudes and longitudes and produce errors in the results. In fact, it is known that residuals in surveys tend to maintain sign over considerable distances, and in some cases estimated uncertainties have been increased accordingly. But we now know a bit more; we still do not know the deflexions in detail, but we have a good idea of their average amount, because in a potential disturbance of high order the mean squares of the two transverse components are together nearly equal to that of the radial component, which we know from the irregularities of gravity. The uncertainty thus becomes calculable; the 10° and 30° variations together will produce an increase of the uncertainty of an estimate of the radius ranging from about 800 metres for a 10° arc to 280 metres for a 30° arc and 66 metres for a 100° arc. I had considerable difficulties in tracing the original determinations; but the outstanding result was that, with the apparent uncertainties found from the survey residuals, the results were plainly discrepant: $\chi^2 = 15\cdot3$ on 6 d.f.* But with an increase of uncertainty due to deflexions, χ^2 came down to 4·4 or 2·4 according as the low harmonics in gravity were allowed for or not. The solution then indicated that Hayford's radius was too large; the equatorial radius was 6378·117 ± 0·119 km. in both cases, Hayford's value being 6378·388 km.

The absolute value of gravity has been redetermined twice lately, at Teddington and Washington, and various cross-comparisons have indicated that the Potsdam determination of 981·274 ± 0·003 cm./sec.^{2} is 10–20 mgal. too high. It appears that the Potsdam workers had corrected for a systematic error that was not there. With a method of reduction that takes account of internal correlation of the errors, I get 981·2633 ± 0·0022. The three absolute measures, with three cross-comparisons, give

$$g_P = 981\cdot2606 \pm 0\cdot0010;\ g_T = 981\cdot1807 \pm 0\cdot0008;\ g_W = 980\cdot0831 \pm 0\cdot0009.$$

$\chi^2 = 6\cdot2$ on 3 d.f. This is slightly on the large side, but not large enough to afford reason against taking the experimental determinations at their face value. The principal British stations are strongly connected with Teddington by recent measures made by the Anglo-Iranian Oil Co. with a gravimeter. Apparently the solution requires all absolute determinations, which are mostly based on the Potsdam standard, to be reduced by about 13 mgal.

If the interior of the earth was in a hydrostatic state, the ellipticity could be found from the precessional constant with a standard error of about 0·08 in the denominator. No other method makes this less than about 1. The hypothesis is certainly false, but the existence of the 10° and 30° variations gives an indication of how far it is likely to be wrong; the effect is to increase the estimate of uncertainty to about 0·31 or 0·61 according as the low harmonics in gravity are rejected or accepted. In either case, contrary to what I had expected, it remains the most accurate single equation for the ellipticity.

---

*An anomaly is the excess of gravity over that given by the international formula, which is an approximate formula that makes the surface $\Psi = C$ an exact spheroid of ellipticity 1/297·0.

* "d.f." means "degrees of freedom", which is number of estimates less number of parameters found from them. $\chi^2 = \Sigma(O - C)^2/s^2$, where s is the standard error of the estimate O.

The lunar parallax has been measured visually, and can also be calculated. Very crudely, $g = fE/a^2$, $n^2 = fE/r^3$; whence $an^2/g = a^3/r^3$. (f is the constant of gravitation; E is the mass of the earth; a is the radius; n is the moon's angular velocity; r is the moon's distance.) Several corrections are needed, and when they are made the result is the dynamic parallax. There has been a slight discrepancy between the visual and dynamical values, but as it was only about 1·4 times the standard error it does not, in any event, appear serious. Here again the possible deflexions of the vertical at Greenwich and the Cape must be taken into account. The final result is that all the data, survey (a and e), the main ellipticity term in gravity, the lunar parallax, and the estimate of the ellipticity from the precessional constant fall nicely into agreement with regard to the uncertainties, whether the longitude terms of low degree in gravity are accepted or not. All the discrepancies can be explained as due to the earth's having been treated as more symmetrical than it is.

The data for the moon's motion have been combined with those for the earth. Again no discrepancy was found; altogether $\chi^2 = 6{\cdot}3$ or $8{\cdot}7$ on 14 d.f. The final results in a compromise solution are

$$a = 6378{\cdot}099 \pm 0{\cdot}116 \text{ km.};\quad e^{-1} = 297{\cdot}10 \pm 0{\cdot}36.$$

$$g = g_0(1 + \beta \sin^2\varphi + \gamma \sin^2 2\varphi);$$

$$g_0 = 978{\cdot}0373(1 \pm 0{\cdot}0000024);\ \beta = 0{\cdot}0052891 \pm 0{\cdot}0000041;\ \gamma = -0{\cdot}0000059;$$

Lunar parallax = $3422{\cdot}419'' \pm 0{\cdot}024''$;
Mass of earth/mass of moon = $81{\cdot}278 \pm 0{\cdot}025$;
Processional constant = $0{\cdot}00327260 \pm 0{\cdot}00000069$.

Except for a and g_0, there is no serious change from accepted values, but the uncertainties are based on additional evidence and more satisfactorily determined.

OBITUARIES

Mr. Richard Elmhirst

RICHARD ELMHIRST died very suddenly on November 13 at Millport after forty-two years of service to the Scottish Marine Biological Association and within a few months of the date when he would have retired. He was the youngest son of the Rev. Robert Elmhirst, vicar of Brotherton, in Yorkshire, and was educated at St. George's School, Harrogate, and at Rossall School. There the bent of his mind was early displayed; he was twice natural history prizeman and was assistant curator of the School museum. In 1902 he proceeded to the Yorkshire College, which had become the University of Leeds before he left in 1905. He took no degree, maintaining throughout life an objection to degrees or appendages of any kind, but with his natural gifts fortified by study under that great teacher and zoologist, L. C. Miall.

Elmhirst had already had experience of museum work at Leeds and at Keighley when he went to Plymouth in January 1906 to undertake, for the Marine Biological Association, the preparation of a collection of marine exhibits for the exhibition held that year at Marseilles. He returned from France to take up an appointment in September as naturalist at Millport on the recommendation of E. J. Allen. It was at Millport that he was to do his life's work. On the resignation of the director, S. Pace, in 1907, he was appointed interim curator, promoted superintendent in 1908 and finally director in 1933. He served with distinction in the First World War as lieutenant, R.N.V.R., in the Dover Patrol.

From 1907 until 1922 Elmhirst was the sole member of the scientific staff at Millport. He had little to maintain him but his enthusiasm as a naturalist in the midst of a wonderful collecting area of sea and shore. Later he had the satisfaction of seeing the Station develop with a fine extension to the buildings in 1939, and even the setbacks of the Second World War made good by major increases in staff and equipment.

Richard Elmhirst was a born naturalist and a most lovable man; and because he was so interested in all living things, his fellow creatures as well as the inhabitants of the shores of the Great Cumbrae and of the waters of the Clyde Sea area, he was a fine teacher. He enjoyed the annual Easter classes where so many students had their introduction to marine biology. I myself must be one of many whose interests were permanently influenced by studying the seashore and its life under his guidance. It was the same with all visitors. He welcomed them with natural hospitality and would go to endless pains to secure the most unlikely of animals, and with a success that brought him as much pleasure as it did the recipient. The Millport laboratory has a tradition of popular teaching, and annually all manner of parties from natural history societies, colleges and schools came—and usually on Saturday afternoons—to be welcomed by him and given lectures and demonstrations or taken for expeditions on the shore. He was known throughout the west of Scotland as a willing and always interesting lecturer.

He never confined himself to any particular group of animals. He knew them all, and the plants as well. The very diversity of his interests was in one sense a drawback. There were so many fascinating things to observe and to investigate that when he had examined one thing he must proceed at once to another and then another. So his published papers, though far-reaching and all of real value, were never so full or so detailed as they would have been had he confined his interests more rigidly. But if he had done so he would never have acquired his amazing breadth of knowledge—and he would not have been Richard Elmhirst.

It was as a man that we remembered him when he was laid to rest on November 16 at Millport, with which his name will be associated so long as the marine station which he built up survives. Our heartfelt sympathy goes out to Mrs. Elmhirst and to his son.

C. M. YONGE

Dr. S. C. Bradford

THE death on November 13 of Dr. S. C. Bradford, following so closely on that of Prof. A. F. C. Pollard, suggests that the elder generation of those who built up the modern scientific information network is passing away, its contribution made.

Samuel Clement Bradford was born in London in 1878, and joined the staff of the South Kensington Museum in 1899, being in the library from 1901 onwards. He worked at this time in what is now the Victoria and Albert Museum. During 1911–14 he had charge of the chemistry collections in addition to his work in the library. During the First World War he was lent first to the National Physical Laboratory and then to the Chemical Warfare Department. He became chief librarian of the Science Library in 1925, with the rank of keeper from 1930. He married Cora Mabel Monnery, who survives him. He leaves no children.

It may well have been Bradford's experience of literature searches during the First World War which led to the activities for which he is remembered. At all events, he proceeded to develop the Science Museum Library as the nucleus of a great central information service, with a vast repository of cards classified by the Universal Decimal Classification. He became persistently active in propaganda for the decimal system, since the scheme would fall to the ground unless an international classification was widely adopted. The British Society for International Bibliography came into being largely through him. National and international meetings were held, culminating in the Oxford gathering of the International Federation for Documentation in 1938.

Meanwhile, one really successful development due to Bradford at South Kensington went on with no need of propaganda. This was the loan system, for after the First World War came the great development of research by industry and government, and this entailed a huge appetite for postal loans. This Dr. Bradford set himself energetically to satisfy. It is indeed ironical to think of the mechanized distributing centre planned from a room which in size and furnishings was one of the all too few survivals of a more spacious and humane conception of library work. It is as seated in this room that his friends will wish to think of him, the brown leather bindings behind the glass, the space bisected by a chemical bench. For Bradford was an active man of science as well as a bibliographer; colloids and the kinetic theory of liquids being among his subjects. Another of his activities will occur to many who met him: the choice rose so often to be seen in his buttonhole marked him for the very active fancier that he was. Music, also, had been an early interest. But basically he remained one of the older museum and library world, deeply concerned with the details of his profession.

Bradford's literary work included various official catalogues, including "Classification for Works on Pure and Applied Science", second edition, 1921; third edition, 1936; "Hand-list of Short Titles of Current Periodicals in the Science Library", fourth edition, 1926; fifth edition, 1938; "Romance of Roses"; "The Science of Rose Growing"; contributions to scientific and technical journals; papers on the kinetic theory of gases and liquids; the molecular theory of solution; colloid solutions; the formation and structure of jellies; the crystallization of gelatin; the Liesegang phenomenon; the classification and indexing of scientific literature; the principles of classification; the organisation of scientific bibliography; and library cataloguing. His final contribution in this last field was the book "Documentation", which appeared not long before his death.

H. T. PLEDGE

WE regret to announce the following deaths:

Dr. J. H. van der Bijl, F.R.S., chancellor of the University of Pretoria, on December 2, aged sixty-one.

Lieut. Oliver Burd, R.N., meteorologist, and Mr. Michael C. Green, general assistant, of the Falkland Islands Dependencies Survey, on November 8.

The Right Hon. J. H. Hofmeyr, chancellor of the University of the Witwatersrand, and president in 1928–29 of the South African Association for the Advancement of Science, aged fifty-four.

NEWS and VIEWS

Industrial Health Research Board

THE following have accepted the invitation of the Medical Research Council to serve as members of the Industrial Health Research Board during the next three years: Sir Frederic Bartlett, professor of experimental psychology, University of Cambridge (*chairman*); Sir Charles Bartlett, managing director, Vauxhall Motors, Ltd.; Prof. R. V. Christie, professor of medicine, University of London; C. R. Dale, Social Insurance Department, Trades Union Congress; Dr. A. N. Drury, director of the Lister Institute of Preventive Medicine; Sir Luke Fawcett, general secretary, Amalgamated Union of Building Trade Workers; Prof. T. Ferguson, professor of public health, University of Glasgow; Sir Claude Gibb, chairman and managing director, C. A. Parsons and Co., Ltd., Newcastle-on-Tyne; Prof. A. Bradford Hill, professor of medical statistics, University of London; Prof. Esther M. Killick, professor of physiology, University of London; Prof. R. E. Lane, Nuffield professor of occupational health, University of Manchester; Dr. A. Massey, chief medical officer, Ministry of National Insurance; Dr. E. R. A. Merewether, H.M. senior medical inspector of factories, Ministry of Labour and National Service; Dr. J. M. Rogan, Medical Research Council headquarters staff: Dr. Donald Stewart, chief medical officer, Austin Motor Co., Ltd.; Mrs. Joan M. Faulkner, Medical Research Council headquarters staff (*secretary*).

The Board is appointed by the Council to advise and assist the latter in that part of its research programme which relates to occupational health. The detailed consideration of research work is in the hands of scientific committees dealing with such subjects as occupational medicine, occupational physiology, occupational psychology, industrial pulmonary diseases, toxicology and statistics. These committees report directly to the Council for purposes of immediate action. The function of the Board itself is that of a reviewing body considering general policy with regard to research over the whole field.

Esperanto and Science

THE British Esperantist Scientific Association has been founded by a body of British scientific workers and technical experts who are interested in the use of Esperanto as an international medium for the discussion of scientific affairs. Before the War there existed an Internacia Scienca Asocio Esperantista; but this body, like so many others, disintegrated during the last ten years, and is only being reconstituted with some difficulty. 'BESA' (as the new Association is popularly called) is taking an active part in this work; meanwhile, however, it also aims at arousing an interest among British men of science in the potential value of Esperanto for the exchange of scientific information and at creating in Great Britain a nucleus of workers who are themselves adepts in the use of the language for scientific purposes. Several of its members are engaged in the compilation of technical vocabularies in various fields—an essential task inasmuch as (though Esperanto has been in use for general purposes for sixty years) there is as a result of the interruption of normal communications in recent times a considerable need for the standardization of many new technical terms which have come into use during this period. The Association has also made informal contacts with Unesco and other international organisations with regard to the whole question of international language. Since its inception in February 1947, the Association (which has an advisory panel of distinguished workers in various branches of science) has held a number of meetings at University College, London. Business proceedings are conducted in English, but technical papers are read and discussed in Esperanto. Membership of the Association is open to all who are interested in the application of Esperanto to science and technology, whether professionally occupied in these fields or not. The president is Dr. J. C. Flugel, of University College, London, and the honorary secretary, Mr. E. D. Durrant, of 15 Beaufort Road, Reigate, Surrey.

Vitamin D Assay

ALTHOUGH specification for the assay of vitamin D_2 by the chick method exists (London: British Standards Institution: B.S.S.911) there is none pertaining to assay on rats, the test animals used in many different laboratories. The Society of Public Analysts and Other Analytical Chemists, and the Society of Chemical Industry therefore set up a joint committee to determine "the fiducial limits that might reasonably be expected in biological assays of vitamin D using rats". British organisations employing this technique were asked to submit statements and opinions based on their own experience, and as a result of the information so collected the joint committee has now issued the following statement: "In the absence of any special circumstances, it is reasonable to expect that assays of vitamin D by the rat method in normal commercial practice should have fiducial limits (calculated to a probability level of 95 per cent) not wider than 60–170 per cent"; and the opinion is expressed that "the result of any assay conforming to these limits should be a commercially acceptable estimate of the true potency of the material assayed". Fuller details are being presented by the committee in the *Analyst* and in *Chemistry and Industry*.

Geophysics in Finland

GEOPHYSICAL studies in Finland on truly scientific lines started early in the eighteenth century, a movement in which an 'invitation' of date 1723 from James Jurin, secretary of the Royal Society, to co-operate in meteorological observation, played a part. An account of the early history of Finnish geophysical studies appeared in 1935 in the first issue of a journal, *Geophysica*, published by the Geophysical Society of Finland, a body founded in 1926. Papers are read at its meetings; but the Society is not in the main a publishing body. *Geophysica* No. 1 (financed by a grant from lottery funds) included, however, three general articles besides the historical summary, and also thirty-six pages of summaries (by the authors) of Finnish geophysical papers published during 1930–34, giving a view (though incomplete) of the then recent Finnish activity in the subject. This view is now extended by the appearance in 1947 of *Geophysica* No. 2, which, like No. 1, is written wholly in English and German. Apart from two short articles on the Finnish Geodetic Institute, 1918–38, and the Isostatic Institute (subsidized, except during the War, by the International Association of Geodesy), the volume is devoted to authors' summaries of Finnish geophysical literature during the period 1935–44. An improvement on No. 1 is the inclusion of alphabetical lists of authors under five subject-headings, which makes the volume very convenient for reference in searching for any recent work done in Finland on these topics. The volume well indicates the extensive and valuable work done in geophysics in Finland during ten troubled years.

Portable Barometer

A PORTABLE barometer made by the well-known clockmaker Daniel Quare (1649–1724) has been lent by Mr. R. Meyrick, of Corbridge-on-Tyne, to the Science Museum, South Kensington. The barometer is an early domestic form of the instrument, in which the tube and cistern are enclosed in a fluted walnut case carried on four metal feet. Thus the instrument can stand on a table, though a ring is also provided for hanging it against a wall. This barometer was the first designed for portability, having been made by Daniel Quare to his own patent specification of 1695. It uses a cistern with a flexible leather bottom which can be compressed by means of a screw so as to fill the barometer tube with mercury and thus avoid the risk of damage when the barometer is moved. To reduce this risk still further, there is a constriction near the top of the tube, to retard the flow of the mercury and thereby reduce the impact of the column on the upper, closed end of the tube. The instrument has a weather scale very similar to that still used on domestic barometers.

An Interesting Hemipterous Insect from New Zealand

IN the first volume of *Dominion Museum Records in Entomology* (Wellington, N.Z.), June 1948, p. 63, Carl J. Drake and J. T. Salmon contribute a short paper entitled "A Second *Xenophyes* from New Zealand". Under the name of *Xenophyes forsteri*, the authors describe a new species of the small and little-known family Peloridiidæ from New Zealand. The family, it may be added, is also known from southern Argentina, Patagonia, Australia and Tasmania. It provides, therefore, an additional link in the evidence from other sources of a direct land connexion between the South American and Australasian continents. Only seven species grouped under three genera of Peloridiidæ are at present known. What little biological evidence there is available indicates that its members feed largely, or wholly, on mosses, and inhabit damp situations. The family was originally placed in the Hemiptera – Heteroptera and, since the antennæ are concealed from view, it was relegated to the series Cryptocerata. Recent research, however, indicates that its affinities lie with the suborder Homoptera and that it represents a separate and new series named by Myers and China in 1929 the Coleorrhyncha. This view is now generally accepted by most students of Hemiptera. The species are all very small creatures the hind wings of which are vestigial or absent. The tegmina occur in probably all the species in two forms, macropterous and brachypterous, although both these types have not yet been found in all cases.

The Solar Apex

Mr. O. R. Walkey has examined the literature on the position of the solar apex (*Mon. Not. Roy. Astro. Soc.*, **106**, No. 4; 1946). Table 1 shows the marked divergences in the positions determined from 1933 to 1941. Mr. Walkey uses as his basis Moore's "Catalogue of Radial Velocities" (*Pub. Lick Obs.*, 18; 1932) and Boss' "General Catalogue" (*Carnegie Pub.*, No. 468; 1937). It is suggested that the divergences just referred to may be partly due to rotation in a probable local cluster which leavens the allowance made for galactic rotation—a view to which some support is given by the increased declination in the apex with increased magnitude of the stars used. Mr. Walkey believes that our ignorance of the actual peculiar motions of the stars, and the consequent assumptions required to fill this gap in our knowledge, may undermine "the refined mathematical edifice built thereon". Using the two catalogues mentioned, he considers the *sense* alone of their respective motions, whether reflecting "pro"-solar motion, or the reverse—"con". In this way he by-passes assumptions for distance (for cross-motions), etc., and also the general assignment of arbitrary limits for acceptable motions. A full explanation of the method appears in the paper, to which reference must be made for details of the method; Mr. Walkey states that the method is a development of that mentioned by Russell, Dugan and Stewart in "Astronomy", vol. 2. As a result of his investigation, involving 40,720 star motions, Walkey's conclusions are as follow: position of solar apex, 1900·0; R.A. 270·2° ± 0·3°, Dec. + 28·7 ± 0·5°. The solar velocity of approach was found to be 20·5 ± 0·6 km./sec., its galactic planar component being 19·0 km./sec. and the normal 7·75 km./sec.

Metal Caps for Test-tubes

We have received from Messrs. Oxo, Ltd. (Thames House, Queen St. Place, E.C.4), samples of metal caps for test-tubes. These caps have been used for some time in their laboratories, and Messrs. Oxo offer to supply them free of charge to other laboratories which ask for them. The caps are intended as a substitute for cotton wool plugs, and Messrs. Oxo claim for them the following advantages: test-tubes of media fitted with the caps remain sterile for long periods; there are no fibres to contaminate the media; tubes fitted with the caps can be sealed with 'Cellophane'; the caps can be labelled with an ordinary pencil and this labelling withstands autoclaving; they are easily removed and replaced and do not stick to the mouths of the tubes; the caps last a long time and can be cleaned by boiling in 0·5 per cent caustic soda, followed by rinsing and drying. The caps appear to be made of an aluminium alloy and are supplied in three sizes to fit standard test-tubes with outside diameters of ⅝, ¾ and 1 in.

Rare and Historic Maps

Mr. Francis Edwards, 83 Marylebone High Street, London, W.1, has issued a catalogue (No. 692) of maps and atlases of the British Isles from the sixteenth to the nineteenth centuries which contains several items of unusual interest. There is a first edition of Camden's "Britannia" with 57 double-page maps, and also a copy of Collins' "Coasting Pilot" of 1693 with 48 maps. Perhaps more noteworthy are several copies of different editions of Speed's atlas, including the rare fully-coloured one, and a first edition of Saxton's atlas of England and Wales. The catalogue also lists a copy of that rarest of all sea atlases, "Arcano del Mare" of Robert Dudley, Duke of Northumberland, with 133 maps, and plans and diagrams.

Geology in Scotland: Swiney Lectures

The first half of the course of Swiney Lectures on geology are being delivered (December 6–17) by Dr. Douglas A. Allan, director of the Royal Scottish Museum, at the Museum itself in Chambers Street, Edinburgh. The general title covering the twelve lectures is "The Geology and Scenery of Scotland". This is the first time that Swiney Lectures, which are under the direction of the British Museum (Natural History), have been given outside London, and Mr. N. B. Kinnear, director of the Museum, presided at the opening lecture. The last six lectures will be delivered at the same place at 5.30 p.m. on Mondays, Wednesdays and Fridays during January 17–28, 1949.

Announcements

Prof. Ernst Gaumann, of the Federal Technical College, Zurich, has been elected *correspondant* for the Section of Botany of the Paris Academy of Sciences, in succession to Dr. A. F. Blakeslee, who has been elected a foreign associate of the Academy.

Prof. E. G. Cullwick, director of the Electrical Research Division, Research Defence Board, Ottawa, will be the first occupant of the new Watson-Watt chair of electrical engineering at University College, Dundee.

Dr. J. L. B. Cooper, of the Department of Mathematics, Birkbeck College, University of London, has been appointed to the University readership in mathematics tenable at the College.

A series of four sessions on the "Educational and Social Significance of the Land" has been arranged by the Association of Agriculture and the University of London Institute of Education, to be held at the latter's headquarters in Malet Street, London, W.C.1. The first session has already been held and the remaining three will be at 10 a.m. on December 11, and February 5 and 19. At each session two lectures of one hour's duration will be delivered, and emphasis will be laid on teaching methods in the middle forms of secondary schools. Admission is 1*s.* per session or 2*s.* 6*d.* for all four, and further details may be had on application to the general secretary, Association of Agriculture, Abbey House, Victoria Street, London, S.W.1.

A series of three Christmas Lectures, especially adapted for a juvenile audience of from twelve to seventeen years of age, will be given in the Royal Photographic Society's House, at 16 Princes Gate, London, S.W.7, on December 29, 30 and 31, 1948. A special house exhibition, comprising Nature subjects, is being arranged by Mr. Oliver Pike to coincide with the lectures. The lecturers and subjects will be as follows: "The Chemistry of the Process", by Dr. H. Baines; "Formation of the Image and Making the Negative and Print", Part 1, by Mr. K. H. Gaseltine, and Part 2 the next day. Admission will be free but by ticket only, obtainable on application to the Secretary of the Society at the above address.

Artificial Stimulation of Rain

DURING the past summer here, the South African Council for Scientific and Industrial Research, with the assistance of the Division of Meteorology and the South African Air Force, arranged a series of experiments to examine the practical possibilities of the artificial stimulation of precipitation.

As natural conditions in the Transvaal in summer are particularly favourable for the development of convective cloud, the experiments were directed mainly to an investigation of the effects produced by the release of 'dry ice' into developing cumulus cloud or incipient thunderstorms.

Experiments were carried out from January to April, 1948, on days on which fairly numerous thunderstorms were expected to occur, and selected clouds were 'seeded' with 'dry ice', development being observed by means of a 3-cm. radar, the aerial system of which consisted of a rotating parabolic reflector producing a 2°-beam, the elevation of which was manually adjustable. Display was by PPI, and arrangements provided for the aircraft position to be indicated directly on the screen. A photographic record of the screen on 16-mm. film was made automatically at predetermined intervals.

'Dry ice', crushed to $\frac{1}{4}$–$\frac{3}{4}$ in. mesh, was dropped within, or 200–400 ft. above the tops of, thirty-six cumulus clouds on six days, and the following is a summary of the results of the photographic record of the radar display.

1. No echoes observed	4	occasions
2. Echoes doubtful owing to permanent echoes and close-in clutter	8	,,
3. Echoes of less than 15 min. duration :		
(*a*) First appearance in less than 30 min.	4	,,
(*b*) ,, ,, between 30 and 90 min.	4	,,
(*c*) ,, ,, after more than 90 min.	2	,,
4. Echoes of more than 15 min. duration :		
(*a*) First appearance in less than 30 min.	7	,,
(*b*) ,, ,, between 30 and 90 min.	5	,,
(*c*) ,, ,, after more than 90 min.	2	,,

'Dry ice' was dropped when air temperatures were between 7° F. and 29° F., and at a rate ranging from 20 lb. to 200 lb. per minute, into cumulus cloud which observation showed to consist of supercooled water droplets. Echoes from clouds seeded at the lower temperatures occurred more consistently than those from clouds seeded at temperatures nearer freezing; but from the limited number of experiments, no conclusions could be reached regarding the comparative effectiveness of the different quantities of 'dry ice' employed.

The experiments indicate that the use of 'dry ice' undoubtedly had the effect of inducing precipitation at an earlier stage in the life of the cloud than is normally the case. Such precipitation was often associated with lightning and, on one occasion at least, lightning was observed below a cloud fifteen minutes after it had been seeded, although its imminence was not suggested by the development and general appearance of the cloud.

The information at our disposal is not sufficient to draw any conclusions as to whether this stimulated precipitation affected the intensity of rainfall which would probably have occurred later from the seeded clouds, and whether it prolonged its duration or extended the area over which it fell.

Temperature observations made during these flights with a sensitive electrical thermometer show remarkably large temperature variations in horizontal flight. In one case a difference of 7° F. during a few miles of horizontal flight in clear air at about 20,000 ft. was noted. Temperatures recorded within cumulus clouds were frequently lower than those observed in clear air at the same pressure just outside the cloud.

We wish to thank the Director of the Division of Meteorology, the Director-General and officers of the South African Air Force, and Messrs. National Chemical Products for their generous co-operation and help in these experiments.

Condensation of Water Vapour Below 0° C.

AN apparatus has been constructed which permits ultra-microscopic observation of individual condensation nuclei in an expansion chamber. The chamber may be cooled by immersion in a low-temperature bath, and the air in it supersaturated on further cooling by sudden small expansions. The object has been to study cloud formation at temperatures below 0° C., particularly in order to discover under what conditions ice crystals appear and whether they are the result of direct sublimation from vapour to ice or of the condensation and subsequent freezing of water droplets. This question has considerable meteorological importance, since the presence of ice crystals in a cloud is often supposed to be essential to the development of rain.

Outdoor air. Experiments with outdoor air have shown that above − 32° C. condensation occurs almost entirely in the form of water droplets, and that ice nuclei, if present, do not exceed 1 per c.c. When the final temperature at the end of the expansion falls below a threshold, which appears to vary between − 32° C. and − 35° C., clouds are usually seen to contain ice crystals in numbers up to 20 per c.c., although water droplets remain far more numerous and may be about 1,000 per c.c. The number of ice crystals does not noticeably increase when final temperatures are lowered from − 35° C. to − 40° C., nor with increasing supersaturation. Between − 41° C. and − 42° C., however, a very sharp increase occurs, and below − 42° C. clouds are composed mainly, if not entirely, of ice crystals.

An important feature of all ice crystal formation in outdoor air is that it occurs only when the air, initially saturated with respect to ice, is cooled by expansion to the dew-point (to saturation with respect to water). This strongly suggests that the crystals are formed not by direct sublimation but by the condensation and immediate freezing of water droplets (no case has been observed of the freezing of a fully grown water droplet). It is therefore proposed that such ice nuclei should be known as 'freezing nuclei', and that the term 'sublimation nuclei' should be reserved for any which permit sublimation from vapour to ice strictly at the frost-point.

The ice crystals formed in outdoor air do not, on evaporation, leave behind any sublimation nuclei. If the temperature of the chamber be raised gradually, clouds again appear mainly as water droplets as soon as final temperatures fail to reach − 41° C.

Cleaned air. Experiments were made in air from which the great majority of nuclei had been removed by filtration. Down to − 55° C. and with expansions of ratio up to 1 : 10 (the limits obtainable), condensation or freezing occurred only on the few nuclei remaining. Irradiation of the chamber with gamma rays from a radioactive source produced no effect. This is in contradiction to the observation of Cwilong[1].

Contaminated air. The threshold at − 41° C. has been observed not only in outdoor air but also in cleaned air contaminated with a wide variety of artificial nuclei, including those from sprayed sodium chloride and sodium nitrate solutions and from a red-hot platinum wire.

Certain nuclei, however, have been found to stimulate ice formation at higher temperatures. Silver iodide, the effect of which on supercooled water fogs has been reported by Vonnegut[2], provides, when volatilized, freezing nuclei active at temperatures as high as − 6° C.

Only one instance of true sublimation has yet been observed. This was on nuclei produced by a spray of cadmium iodide solution, but only after an ice cloud had been formed on them by expansion to a temperature below − 42° C. The ice crystals thus formed left behind, on evaporation, small particles which acted as true sublimation nuclei at temperatures up to − 10° C. Further warming to − 9° C. caused a 'melting' of these nuclei, which then reverted to giving only water droplets, even on subsequent cooling to − 25° C. It may be noted that the freezing point of a saturated solution of cadmium iodide, in bulk, is in the neighbourhood of − 9° C.

Both silver iodide and cadmium iodide occur in hexagonal crystals which have lattice constants within 7 per cent of those of ice-I.

Nuclei from rain-water. Some recent experiments on the nuclei produced by a spray of rain-water collected during a thunderstorm have revealed the presence of small numbers of nuclei which gave ice crystals at temperatures as high as − 20° C., but which were evidently not common enough to be detected by normal experiments on outdoor air. These may be the nuclei discovered by Findeisen[3], though it was clear that they acted as freezing, and not sublimation, nuclei.

My thanks are due to Lord Cherwell for enabling me to work at the Clarendon Laboratory; and to the Department of Scientific and Industrial Research for a maintenance grant. It is a pleasure to acknowledge my debt to Prof. G. M. B. Dobson for his continued interest and valued advice on many occasions.

A Concentration of Uranium in Black Muds

In the Cambrian black shales of the Oslo area, there is a considerable concentration of uranium, analyses values ranging from 25 to 180 gm./ton. (These and the following uranium analyses were made at the Norwegian Defence Research Institution, which has given permission for their publication.)

An interesting problem is how far a concentration is going on in the present-day black muds formed under anaerobic conditions. There is a large number of land-locked waters around the Norwegian coast, in which these black muds are deposited[1].

During the summer of 1947, I re-investigated these fjords, and the uranium content of some mud samples was determined. All analyses are made by the ether-extraction method and are thus independent of the radium content. In such recent sediments uranium and radium are not in an equilibrium.

The localities have already been described[1], and are here arranged according to the quantities of uranium found. The depth is also stated, as well as the content of hydrogen sulphide and oxygen in the deep waters.

Locality	Depth from which sample is collected (m.)	Content of uranium (gm./ton)	Maximum hydrogen sulphide or minimum oxygen in deep waters (cm.^{3}/l.)
Topdalsfjord	65	60	*c.* 1 H_2S
Søndeledpoll	18	50	5·4
Isefjærfjord	26	50	7·9
Hellefjord	70	40	40·7
Framvaren I	160	40	199·5
Framvaren II	160	35	199·3
Vestrhusfjord	53	35	9·9
Mortensfjord	34	20	1·6
Drammensfjord	117	15	4·8
Oksefjord	81	13	3·2 O_2

There seems to be a definite connexion between drainage from granite areas and uranium content in the black muds, this being most conspicuous with the record value of 60 gm./ton in Topdalsfjord, into which empties a large river draining extended granite areas.

The precipitation probably starts by the formation of sulphide on the interface between the upper ventilated brackish waters and the salt waters of the deep, containing hydrogen sulphide.

By comparing my old core samples with echo soundings taken during the summer of 1948, I was able to ascertain the thickness of the layers of blackish muds to range from less than a metre up to some 20 metres in a few isolated places.

Two of the three fjords which stand apart by their low values are, as a rule, quite well ventilated, while in the Drammensfjord the muds are not very black and there is probably a considerable redeposition of clay from the shores. Even here there is some concentration in relation to the granitic batholith in which the Drammensfjord is situated; but from which it receives only a very small part of its freshwater supply, and in which the uranium content is some 10 gm./ton.

Range-Energy and Other Relations for Electrons in Kodak Nuclear Plates

KODAK Nuclear Track plates of type *NTP* 2, 30 μ in thickness, have been exposed in a low-resolution β-ray spectrograph using uniform magnetic fields of 279 and 302 oersteds. The focused line had a half-breadth of about 1 mm. The rays entered the plate at a grazing angle, the central ray meeting the plate at 6°. 'Line' sources of thorium (B + C) and radium E were used to provide continuous spectra. Exposure times were such as to give, in the 80-keV. energy region, about 2 × 10^5 β-rays per sq. cm. on a surface normal to the central ray. The plates were developed for 20 min. at 18° C. in 'Kodinol' developer.

Emulsions of two different sensitivities were used, the normal *NTP 2a*, and an experimental emulsion having larger grains and higher sensitivity than the *NTP 2a*. The chemical constitution of the two emulsions was the same. In the *NTP 2a* plates, electron tracks could be followed easily up to 50 keV., and with some difficulty up to 80 keV. energy. In the more sensitive emulsion, the upper energy limit for the range measurements was set by the thickness of the emulsion. The longest observed track was of 94·4 μ with corresponding energy almost certainly greater than 150 keV. (see below). Fig. 1, from a radium E plate, shows a 'background' track (probably of a secondary electron due to high-energy *Bremsstrahlung*). This track is 81·4 μ long and contains about 65 grains. Fig. 2 shows an 80-keV. track from radium E (27·8 μ and 32 grains).

Measurements were made of the ranges of unbranched tracks (a branch could not be identified with certainty if its energy were below about 20 keV.) starting in the surface of the emulsion and having an initial direction within 40° of the central ray direction. Working from grain to grain, observations were made of projected lengths and differences of depths. Depth measurements were corrected for shrinkage of the emulsion in processing. The range data from the higher sensitivity plates are given in Table 1. Because of the limited thickness of the emulsion, the 100-keV. range may be somewhat low; and is therefore enclosed in brackets.

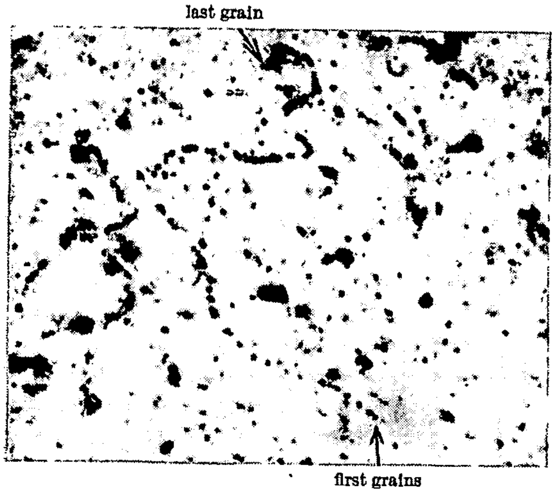

Fig. 1. Electron track of length 81·4 μ: magnification 1,260

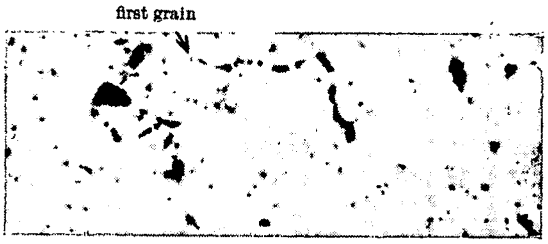

Fig. 2. Electron track of 80-keV. energy; magnification 1,260

Table 1

No. of tracks observed	Mean energy of tracks (keV.)	Mean range of tracks (μ)*	Standard deviation of ranges	Mean No. of grains per track*	Standard deviation of number of grains
25	30	6·90±0·33	1·67	10·8±0·4	2·0
25	40	11·00±0·57	2·84	14·4±0·4	2·0
25	50	15·78±0·50	2·51	20·4±0·7	3·6
25	60	22·15±1·12	5·62	22·4±1·0	4·9
25	80	32·65±1·55	7·74	35·5±1·4	6·9
25	100	(42·09±1·99)	9·94	41·0±1·6	7·9

* With standard error.

The grain density along the 100-keV. tracks was analysed in 5 μ portions of the tracks, working backwards from the last grain of the track. The results are given in Table 2.

Table 2

Portion of track from the last grain	Mean number of grains per 5 μ*	Standard deviation of number of grains
0–5 μ	7·0±0·3	1·7
5–10	5·3±0·3	1·3
10–15	5·2±0·3	2·5
15–20	4·6±0·3	1·3
20–25	4·3±0·2	1·0
25–30	4·3±0·3	1·3
30–35	4·1±0·3	1·1
35–40	3·7±0·3	1·0

* With standard error.

The relative stopping power of the emulsion may be defined as $\Delta R_a/\Delta R$, where ΔR_a is change of range in air at 760 mm. mercury pressure and 15° C., and ΔR is change of range in emulsion for the same change of energy of the β-particles from V_A to V_B. Thus defined, the relative stopping power is a function of the mean energy $V = \frac{1}{2}(V_A + V_B)$. Values of relative stopping power given in Table 3 were deduced from the data in Table 1 and from calculated mean ranges of electrons in air given by Tsien, Marty and Dreyfus[1], and shown by Tsien[2] to be in close agreement with experimental values in the region of energy up to 50 keV. If the 100-keV. range in Table 1 is low, the 90-keV. stopping power in Table 3 will be high.

Table 3

V in keV.	Relative stopping power of emulsions, with standard error
35	2640± 420
45	2720± 430
55	2290± 440
70	3130± 570
90	(3840±1030)

The Superconductive Transition

In 1931 de Haas and Voogd[1] showed conclusively that the electrical resistance of a single crystal of very pure tin vanishes discontinuously at the transition temperature. In this experiment the external magnetic field was zero, and the transition curve was extrapolated to zero measuring current. They showed also that physical or chemical impurity produces an extended transition region. Since then it has been generally assumed[2] that such an abrupt change of resistance also takes place when the transition occurs in a (longitudinal) magnetic field, extended transitions being ascribed to impurities. Experiments carried out in this Laboratory[3,4] on very pure lead exhibiting transitions extending over a wide range of magnetic field cast doubt, however, on the validity of this assumption.

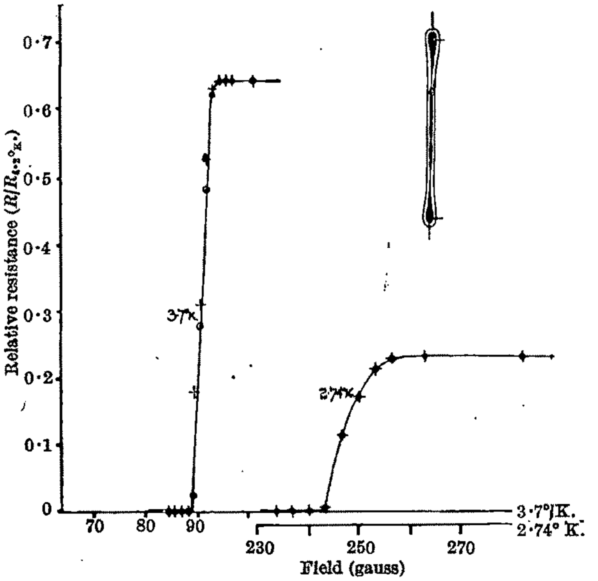

Fig. 1. ○ Ascending; + descending

The true shape of the transition curve is clearly of fundamental significance when analysing the mechanism of the disappearance of the electrical resistance, and we have therefore investigated this problem more carefully. Specimens of very pure tin, lead and mercury which had been prepared *in vacuo* were examined in a longitudinal magnetic field. Preliminary experiments showed that the way in which the leads were attached strongly affected the transition, and finally a method was adopted (to be described in detail elsewhere) by which the potential leads were attached free of strain, without solder and without causing distortion of the magnetic field over the length of the specimen. Under these conditions, in all three metals, the transition curves were of a similar general shape (see Fig. 1). The width of the transition region increases rapidly with the *absolute* value of the critical field (H_c), which means that for a given value of H_c/T a transition in lead is more extended than in tin. Incidentally, this behaviour makes it clear that the transition broadening cannot be simulated by inhomogeneities in the external field. The ultimate criterion for the purity of our specimens was, in the case of tin, provided by comparison of the transition in zero field with those observed by de Haas and Voogd[1]; this showed that our specimen corresponded to their purest single crystal.

It was remarkable, in view of the purity of our specimens, that in no case did we observe hysteresis, a phenomenon commonly ascribed to the transition of pure single crystals. It had been suggested by one of us[5] that resistance hysteresis[6] may be due to the geometrical shape of the ends of the wires, and we therefore investigated a mercury specimen which ended in bulbs carrying the contacts. In every other respect its preparation was identical with the specimen of Fig. 1, thus ensuring similar purity and crystalline state. The result, illustrated in Fig. 2, shows quite marked hysteresis with *discontinuous* jumps, thereby demonstrating that these features are produced, in fact, by the overall geometry of the specimen. A full explanation of this curious behaviour cannot be provided at this juncture. A most puzzling feature is that on occasion the whole transition from zero to normal resistance, when hysteresis is present, can cover a narrower range of magnetic field than the reversible transition of the straight specimen.

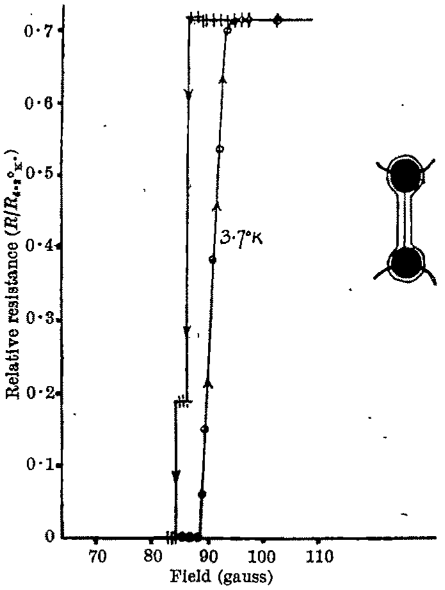

Fig. 2

Summarizing our results, we have found no evidence whatever (once the disturbing effect of geometrical shape is removed) that either discontinuous change of resistance or hysteresis are to be regarded as characteristic attributes of the superconductive transition in a magnetic field.

Measurement of Alkaline Earth Ion Concentrations by Rennet Action

THE relatively high temperature coefficient of the second or cationic precipitation stage of rennet action on casein allows its separation from the first or enzymic stage to be made by appropriate choice of temperatures[1]. Thus the first stage can be completed at 0–5° C., and the second afterwards initiated at about 35° C. The coagulation time at the higher temperature, extremely sensitive to variations in alkaline earth ion concentration within a fairly narrow range, can then serve as a measure of such concentrations.

Measurements are made on solutions of the appropriate caseinate, relatively small volumes of which have been brought, by dialysis at 0–5° C., into equilibrium with the solutions to be tested and a suitable range of standards. Solutions tested and standards for comparison should both agree approximately in content of ions of other valencies, the presence of which, particularly of polyvalent anions, influences the alkaline earth ion concentration for coagulation.

Determinations made by this method of the dissociation constants of calcium and barium citrates, $K = [\mathrm{Me}^{++}] \times [\mathrm{Citr.}''']/[\mathrm{Me\ Citr.}']$, at 2° C. and an ionic strength μ 0·03 give the values $0{\cdot}35 \times 10^{-3}$ and $1{\cdot}2 \times 10^{-3}$ respectively, in fair agreement with those obtained by other methods[2,3].

A fuller account of this work with further applications will appear elsewhere.

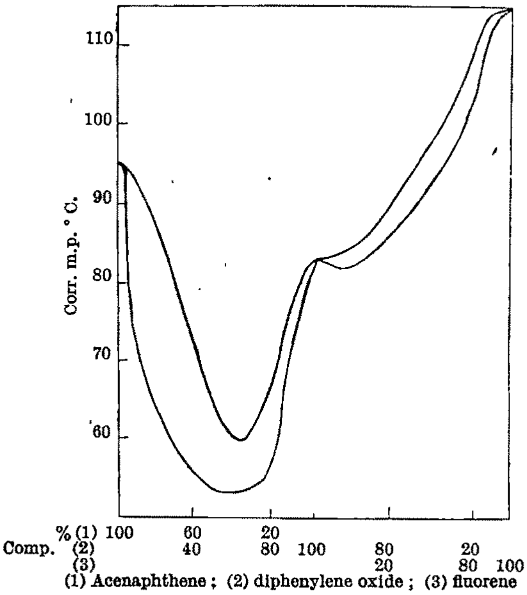
Purity of Diphenylene Oxide (Dibenzofuran)

WE wish to direct attention to the anomalous melting points (82–87° C.) quoted in the literature[1-7] for diphenylene oxide. It is likely that these anomalies are due in part to the mode of formation, and we have examined the particular cases of the isolation of diphenylene oxide (*a*) from coal tar distillates, and (*b*) by the distillation of phenol over litharge[2].

In the latter case, we isolated diphenylene oxide (styphnate, m.p. 139° C.), corresponding to the classical formula $C_{12}H_8O$, of melting point 82·8–83° C. (corr.)—not 87° C. as found by Gallewsky and afterwards by Cullinane. The melting point remained unchanged by further crystallization from alcohol and/or acetic acid, and ultimate analysis gave carbon 85·3 per cent, hydrogen 5·0 per cent.

The isolation of diphenylene oxide from coal tar is closely attended by the lower boiling acenaphthene ($C_{12}H_{10}$, melting point 95° C., boiling point 278° C.) and the higher boiling fluorene ($C_{13}H_{10}$, melting point 114–115° C., boiling point 293° C.). The accompanying graph illustrates equilibrium diagrams, based on pure components, which we have constructed using the thaw-melt method for the systems acenaphthene–diphenylene oxide, diphenylene oxide–fluorene.

It will be noted that diphenylene oxide isolated from coal tar and possessing a melting point lower than 82° C. is probably contaminated with acenaphthene, a higher melting point indicating probable contamination with fluorene.



It is where fluorene is the contaminant that caution is needed in describing the purity of diphenylene oxide, for up to 20 per cent contamination changes the melting point but little from 82·8° C. From the graph, coal tar diphenylene oxide with a melting point of 86° C. would contain about 35 per cent fluorene: this is roughly substantiated by our ultimate analysis of such a sample (carbon, 88·0 per cent; hydrogen, 5·2 per cent), which can be calculated to correspond with a mixture of 7 parts of diphenylene oxide and 3 parts of fluorene.

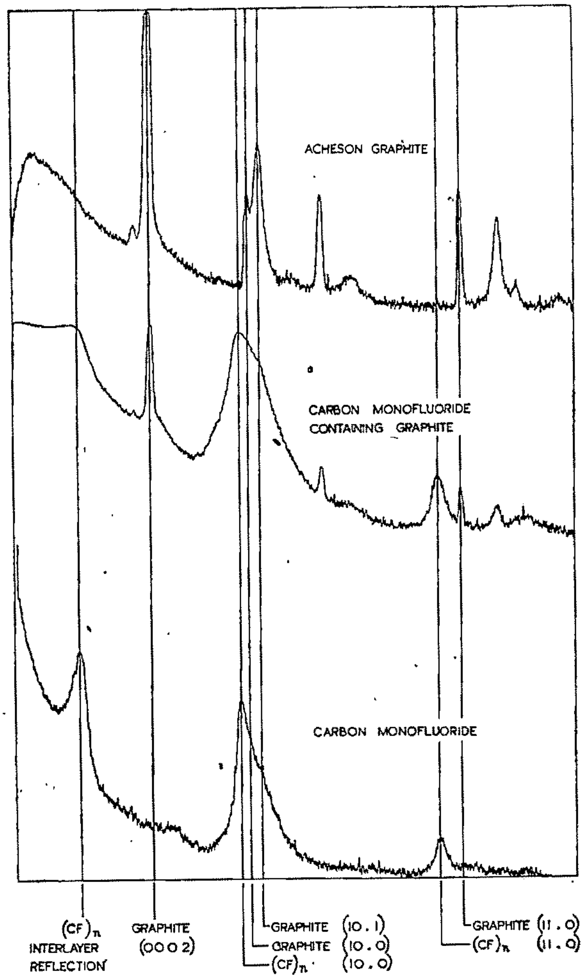
Structure of Carbon Monofluoride

Ruff and Bretschneider[1], in collaboration with Ebert, reported that the X-ray diffraction pattern of carbon monofluoride, $(CF)_n$, had similar (*hk.*0) reflexions to graphite, but that the (000*l*) and other reflexions dependent on the *c* or carbon interlayer spacing were absent. From this they assumed that in carbon monofluoride the graphite structure is retained with expansion perpendicular to the carbon layers and, from a determined density of 2·39, calculated the carbon interlayer spacing to be 8·17 A. They postulated that the fluorine atoms acquire electrons from the carbon rings and that the ions so produced lie in a closely packed structure in six parallel layers between each pair of carbon planes requiring a theoretical carbon interplanar spacing of 8·05 A. Although, such a structure could reasonably account for the low electrical conductivity and explosive decomposition of the compound, it is very doubtful, as pointed out by Bigelow[2], whether such an arrangement would have even limited stability. Bigelow proposed an alternative structure in which the fluorine atoms lie in two parallel planes about each plane of carbon atoms, to which they are linked by polarized covalent bonds. Assuming a normal C—F bond of about 1·4 A., the excessively high spacing of 5·3 A. between the planes of fluorine atoms was explained by electrostatic repulsion resulting from the polarization.



Carbon monofluoride has recently been prepared in this laboratory by the action of fluorine on Acheson graphite at temperatures between 420° and 450° C. The product is grey-fawn in colour, has an analysis of 37·2 per cent C, 61·2 per cent F (theoretical for CF: 38·7 per cent C, 61·3 per cent F) and a maximum density determined by immersion of 2·78 gm. per ml.: this density is considerably greater than that reported by Ruff and Bretschneider. X-ray diffraction photographs of this material are also rather different from those described by Ruff and Bretschneider. Photometric plots of the carbon monofluoride pattern, together with plots of the original Acheson graphite and a sample containing some free graphite for comparison, are shown in the accompanying figure. Carbon monofluoride shows fairly intense low-angle scattering terminated by a broad line (not reported by Ruff and Bretschneider) corresponding to an interplanar spacing of about 6·0 A. In addition, it is seen that the other two strong reflexions with interplanar spacings of 2·23 and 1·30 A. do not coincide with the (10.0) and (11.0) reflexions of graphite, which have spacings of 2·14 and 1·24 A. respectively. The ratio of these two spacings for carbon monofluoride is 1·716 against the theoretical 1·732, that is, $\sqrt{3}$, for $d_{(10.0)}/d_{(11.0)}$ in a hexagonal lattice. It therefore seems probable that the carbon atoms in carbon monofluoride are arranged similarly to those of graphite, with an expansion of the C—C distance and a slight distortion from the true hexagonal arrangement. This hypothesis is supported by the observation of two very weak reflexions with spacings 1·11 and 0·84 A. which can be indexed as (20.0) and (12.0) respectively. The calculated average C—C spacing is 1·49 A., compared with the value of 1·42–1·43 A. for graphite.

With the expanded hexagonal lattice, the corresponding *c* or carbon interlayer spacing calculated from the determined density of 2·78 is 6·3 A.; and it is reasonable to assume that the measured spacing of 6·0 A. corresponds to this dimension in the carbon monofluoride structure, since the above density is likely to be a minimum. The increase of the C—C distance to 1·49 A. suggests the loss of part of the double-bond character of this link, and supports Bigelow's suggestion of the formation of a polarized C—F covalent link. Taking the C—F distance in this bond as about 1·5 A., as against the normal value of 1·43 A., the distance between the fluorine planes would be 3·0 A., which is a reasonable polarized van der Waals' separation. The marked change in the intensity ratio of the (10.0) : (11.0) reflexions from 8 : 10 in graphite to 10 : 1 in carbon monofluoride, and the observation of the (20.0) and (12.0) reflexions, support the probability of a fairly rigid C—F bond in carbon monofluoride; although the actual positions of the fluorine atoms cannot be deduced with any certainty. The absence of general (*hk.l*) reflexions may be caused by a turbostratic arrangement[3] of the carbon/fluorine layer-plane units. This may also account for the falling off at higher reflexion angles, usually associated with cross-lattice reflexions[4], of the (10.0) reflexion; but this is difficult to reconcile with the symmetrical (11.0) reflexion, unless the matter is further complicated by the slight distortion from the true hexagonal lattice.

Calculation of crystallite size from the line broadening shown in the diffraction patterns gives 20–40 A. in a direction perpendicular to the carbon layers and about 50–80 A. in the layers for carbon monofluoride, compared with an approximate 200 A. for the original graphite. This marked decrease in crystallite size is consistent with the reduced van der Waals' forces and the partial utilization of the π-electrons of the graphite structure in the formation of C—F bonds.

Note added in proof. We have since seen a review of the work by Rüdorff and Rüdorff[5], but not their original papers. Our experimental results are essentially similar to theirs, but it is difficult to reconcile their proposed 'hydroaromatic giant molecule' structure with the marked change in reflexion-intensity ratio reported by us.

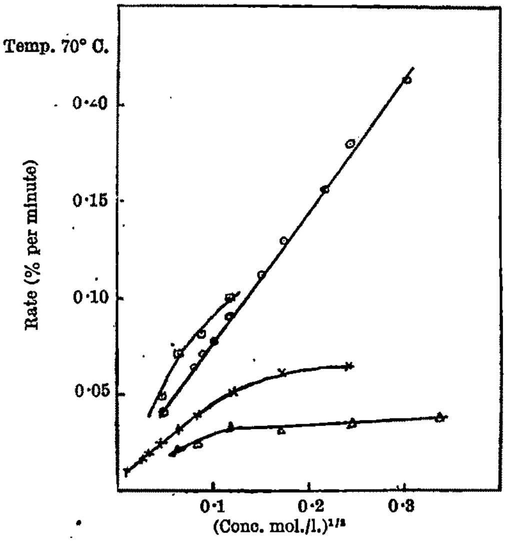
Peroxide Catalysed Vinyl Polymerization

In recent months the importance of the reactivity of the free radicals in polymerization systems has been stressed, in particular the ability of a free radical both to initiate and terminate reaction chains[1]. The emphasis, however, has been on the ability of the radical in question to terminate the growing chains[2], and it is the object of the present communication to direct attention to the lowered rate of initiation of growing chains which results from the use of certain catalysts.



⊙—⊙—, Benzoyl peroxide.
△—△—, Di-*m*-nitrobenzoyl peroxide.
×—×—, *m*-Nitrobenzoyl benzoyl peroxide.
□—□—, Di-2,3,4,5-tetrachlorobenzoyl peroxide.

A feature of peroxide catalysed vinyl polymerizations is that the rate of reaction is proportional to the square root of the catalyst concentration. This, however, is true only for catalysts which generate active free radicals, when the catalyst is used over a wide range of concentrations. The results given in the accompanying graph show that in the polymerization of styrene using di-*m*-nitrobenzoyl peroxide, *m*-nitrobenzoyl benzoyl peroxide and di(2,3,4,5-tetrachlorobenzoyl) peroxide this relationship does not hold. Initial rates of reaction were determined, as the rate fell off fairly rapidly with time in the case of these poor catalysts. Benzoyl peroxide gives a good linear agreement. The observed deviation from linearity occurs with catalysts which give radicals of low activity. (It will be shown again that the activity of a radical is related to the distribution of electron density; thus electron repelling substituents increase the reactivity of a radical, and electron attracting substituents lower the reactivity. Mesomeric effects either supplement or reverse the inductive effect, depending on the direction of electron transfer.)

When incorporated in the kinetic scheme:

$$\begin{array}{llll} & C & \xrightarrow{k_i} & R. \\ R. + & M & \xrightarrow{k_p'} & P_1. \\ P_1. + & M & \xrightarrow{k_p} & P_2. \\ P_r. + & M & \xrightarrow{k_p} & P_{r+1}. \\ P_r. + & P_s. & \xrightarrow{k_{t_1}} & M_{r+s} \\ P_r. + & R. & \xrightarrow{k_{t_2}} & M_r \\ R. + & R. & \xrightarrow{k_{t_3}} & R_2 \end{array}$$

application of the stationary state method of analysis used by Melville and others[3] gives, when the three termination coefficients are considered to be equal (k_t) (the terms having their customary significance):

$$\Sigma(P_r.) = \frac{k_p'(M)(R.)}{\sqrt{k_i k_t (c)}},$$

$$(R.) = \frac{k_i(c)}{\{k_p'(M) + \sqrt{k_i k_t (c)}\}}.$$

Thus the reaction-rate:

$$-\frac{dM}{dt} = k_p'(M)(R.) + k_p(M)\Sigma(P_r.)$$

$$= k_p'(M)\sqrt{\frac{k_i(c)}{k_t}}\left\{\frac{k_p(M) + \sqrt{k_i k_t(c)}}{k_p'(M) + \sqrt{k_i k_t(c)}}\right\}$$

This reduces to the usual form for zero-order initiation when $k_p' = k_p$. This expression gives a linear relationship between the reaction-rate and the square root of the catalyst concentration only when the concentrations used are very small or when k_p' and k_p are nearly equal. To suggest, as has been done, that the three termination constants are equal is a great over-simplification since, for definite values of k_p and k_t, at low concentrations of catalyst the rate would be dependent upon $\sqrt{k_i(c)}$, which is probably not true. However, preliminary results from the intrinsic viscosities of the polymers indicate that these fall normally with increase in catalyst concentration, as would be predicted from the above scheme.

Also:

$$\overline{P_n} = \frac{V\,(\text{prop.})}{V\,(\text{init.})} = \frac{(M)\{k_p'(R.) + k_p\Sigma(P_r.)\}}{k_p'(M)(R)}$$

$$= \frac{k_p(M)}{\sqrt{k_i k_t(c)}}.$$

Red Lead as a Selective Oxidant

Since the fundamental investigations of Dimroth[1], Criegee[2], Malaprade[3] and Fleury[4], lead tetra-acetate and periodic acid as selective oxidants have played an important part in organic chemistry, particularly for the elucidation of the structure of carbohydrates and related compounds and also from the preparative point of view[5]. It has been found now that red lead (Pb_3O_4) in many cases can be used successfully instead of the above-mentioned oxidants either in aqueous acetic acid medium or in organic solvents containing anhydrous acetic acid. It may be supposed that, in the presence of acetic acid, red lead gives rise with a limited velocity to intermediate formation of lead tetra-acetate which, in the presence of a suitable hydrogen donor, will be promptly reduced to lead diacetate. Therefore, the reaction mixture never contains an excess of tetra-acetate. Hence red lead can be more generally used for the oxidation of aqueous solutions than lead tetra-acetate itself, as this rapidly hydrolyses in aqueous medium into uneffective lead dioxide.

For example, as preliminary experiments show, if an aqueous solution of 1 mol. of 1 : 2-propylene glycol is shaken or stirred with a mixture of 1 mol. of red lead and 8 mol. of acetic acid (initial acetic acid concentration 20–25 per cent) at room temperature, the red lead completely disappears within two to three hours and the propylene glycol yields, without formation of lead dioxide, 1 mol. of formaldehyde and 1 mol. of acetaldehyde respectively. One mol. of mandelic acid reacts with 1 mol. of red lead, yielding quantitatively benzaldehyde and carbon dioxide. 1 : 3, 2 : 4-Diethylidene sorbitol yields an aqueous solution of formaldehyde and 2 : 4, 3 : 6-diethylidene *l*-xylose, from which after acid hydrolysis crystalline *l*-xylose was obtained. Under the same conditions glycerol, sorbitol, mannitol, tartaric acid, lactose and sucrose were also smoothly oxidized without formation of lead dioxide. The oxidation of 1 : 2-propylene glycol and mandelic acid, respectively, by red lead in a chloroform solution in the presence of anhydrous acetic acid gave the same result as was obtained in aqueous medium.

On the other hand, ethylene glycol, α-methyl glucoside, diamino-ethane and alanine were not oxidized in appreciable amount in aqueous acetic acid medium. In these cases the red lead changed almost quantitatively within one to two hours into lead dioxide and lead diacetate.

Further studies on the selective oxidative effect of red lead are in progress; the results will be published later elsewhere.

Phosphorylase in Plastids

IN a previous paper[1], a method has been described for the detection of the enzyme phosphorylase in plant tissues. Briefly, it consists of incubating free-hand sections of the tissue, previously freed of starch by starvation, in a buffered solution of glucose-1-phosphate, and subsequent staining in iodine–potassium iodide for the resultant starch. With this method a survey has been made of the distribution of phosphorylase in the tissues of many higher[1,2] and lower[3] plants. An interesting outcome of these observations is the finding that the enzyme is localized solely in the plastids. The evidence may be summarized as follows.

In the leaves of higher plants (*Verbena*, tobacco, squash, potato, corn, soybean, broad bean, castor bean) the enzyme activity is chiefly confined to the mesophyll and the guard cells. In these cells the activity is further limited to the chloroplasts. No reaction is ever found in the nucleus or the general cytoplasm. Each chloroplast may contain one or several loci of activity, which after prolonged incubation fuse to form a large starch grain. Thus the localization of the enzyme corresponds well with the site of normal starch synthesis as observed by Strasburger[4] and Zirkle[5].

Similarly, in the green algæ (*Spirogyra, Zygnema, Cosmaria*) phosphorylase activity is localized in the chloroplasts. It bears no observable relation with the pyrenoids, and is more or less evenly distributed in the plastids. Longer incubation often results in plasmolysis and appearance of fine starch granules outside the protoplast due, perhaps, to injury and leakage.

In plant parts which contain plastids coloured other than green, for example, the petals of nasturtium and the fruit of tomato, the enzyme is again only found in the chromoplasts.

Meristematic cells and cells not fully differentiated generally contain colourless plastids which may turn green later on. It is in these leucoplasts that phosphorylase activity resides, as proved in the embryos and seedlings of soybean, broad bean, potato, corn, etc. Each leucoplast may contain several centres of activity. Long incubation results in filling up the whole cells with starch, and some evidence of plasmolysis. In some cases (soybean) minute starch-like particles can be seen in the cytoplasm. They may have come from broken plastids or are masked original reserve[2], since they also appear in boiled sections and without incubation with glucose-1-phosphate. Sections of these tissues have also been made with the paraffin method and stained to bring out the cytoplasmic components. Again the enzyme activity is traceable to the leucoplasts, and no relation can be established with mitochondria or other cytoplasmic constituents[2].

In plants without visible plastids, for example, the blue-green alga *Oscillatoria* and the fungus *Rhizopus*, phosphorylase activity is found dispersed in the cytoplasm and gives rise to finely divided granules of starch or glycogen[3]. Long incubation results in whole sections of cells stained with iodine. Whether these loci of activity bear any relation to specific cytoplasmic entities remains to be investigated.

The only exception to the phosphorylase-plastid coincidence so far is found in the case of the red algæ. In *Batrachospermum*, reddish-brown staining polysaccharide formed from glucose-1-phosphate appears not in the chromatophores but scattered in the general cytoplasm[3]. It is interesting to note here that, in normal growth, the reserve polysaccharide of these algæ has long been known to be separate from the chromatophores[4]. Hypotheses have been advanced as to the origin of these particles of 'Floridean starch'. They are supposed either to have originated in the cytoplasm itself or grown out of the plastids. Our result supports the first contention, since the responsible enzyme phosphorylase is shown to be outside the plastids.

It may be added here that phosphorylase activity is not normally detectable in plant parts which form no starch. Examples are found in the shoot of onion and the petals of a number of flowers. Plants normally poor in the polysaccharide, for example, castor bean, are also low in phosphorylase activity[1]. In germinating seeds the number of starch grains finally formed in a cell is always smaller than the detectable loci of phosphorylase activity[2].

Summing up, we may say that phosphorylase in plants is localized in the plastids. No activity has been found in the nucleus and, except in the blue-green and red algæ and in fungi, in the cytoplasm.

The result lends support to the statement of Schimper and of Meyer[4] that starch is always formed in the plastids. It confirms also the anticipation of Hanes[6] that starch formation in the plastid (for that matter also outside the plastid, cf. *Batrachospermum*) is due to the phosphorylase mechanism.

Vestibular Effect of Streptomycin in the Mouse

UP to the present, experimental methods have yielded very little information concerning vestibular toxicity due to streptomycin; in medical practice these accidents are very frequent (80–90 per cent of cases treated). Indeed, the fundamental work of Molitor and his collaborators leads to the conclusion that most of the animals used in laboratory work show no recognizable vestibular disturbance, whether as the result of a single heavy dose of streptomycin or of several fractional doses administered over a period of time. According to Molitor[1], dogs are the only animals which show any evidence of cerebellar or vestibular damage comparable to that which has been observed in human beings, whereas mice, frogs, rats and guinea pigs are unaffected. Although Molitor kept under observation a considerable number of animals, we believe that his conclusions should not be accepted as final.

Our researches involved: (1) developing procedures which would enable us to study the vestibular function in the mouse; (2) the development of a suitable technique of labyrinthectomy for these animals, and a study of the phenomena which follow upon this operation, whether unilateral or bilateral; (3) the study of the reactions of a mouse upon receiving a single heavy dose of streptomycin or fractional doses over a period of time. By proceeding on these lines, we have been able to demonstrate a vestibular toxicity of streptomycin in the mouse, moderate in the case of acute intoxication, clear in the case of chronic intoxication[3]. When a heavy dose is administered, the response to the rotation test is in the nature of hyper-excitability. In chronic intoxication (30 mgm. in two daily doses), after about a week, a syndrome appeared which was progressively accentuated, and reproduced, in a lesser and variable degree, the effects of destruction of the labyrinth on both sides, namely, agitation, violent movements of the head in a vertical plane, absence of reaction to rotation, circling or waltzing, total loss of equilibrium and inevitable drowning in the swimming test.

In the mouse, then, the vestibular apparatus is remarkably sensitive to the action of streptomycin, a circumstance highly favourable for the study of this action, which at present is still very obscure.

Streptomycin is one of the two substances which are known to have specific toxic properties on the vestibular apparatus, the other being arsacetin, as Ehrlich[4] discovered when he described the 'artificial' dancing mouse. There appear to be no other compounds which, in the same conditions, display such a property.

Permeability of Muscle Cells

SINCE the advent of artificial radioactive elements, a considerable amount of work on the exchange of labelled ions or molecules against unlabelled ones of the same chemical nature has been carried out on biological material. Krogh has reviewed[1] a number of applications of the technique to exchanges between living cells and their surroundings, and Ussing[2] reports results obtained for the exchange of sodium between isolated muscle and Ringer solution. The remarks made by A. V. Hill[3] concerning measurements of so-called permeability of tissues appear to have been overlooked. He emphasized that diffusion might play the most important part in determining the rate of transfer of dissolved substances from lymph to tissue, even when the size of the tissue is only that of, say, a frog sartorius muscle. It appears, therefore, necessary when attempting to study cell-wall permeability either to use single cells, or to make allowance for the effect of diffusion being the means by which the extra-cellular fluid comes into eventual equilibrium with the fluid surrounding the assembly of cells. Experiments made *in vivo* will be less affected by the retarding influence of diffusion than will those made *in vitro*. This is because in the former case the blood-flow through the capillaries brings the substance being investigated into the interior of the tissue.

We have been making measurements of the rates of exchange of sodium and potassium between isolated frog sartorii and the surrounding medium. Equations describing the time-course of the combined permeation-diffusion process have been obtained. These allow the calculation of the apparent diffusion constant of sodium in the extra-cellular space of the muscle, and of the permeability to sodium and potassium. The apparent diffusion constant for sodium is $2{\cdot}0 \times 10^{-6}$ cm.^{2}/sec., which is a third of the value in free solution; this would correspond to the ion having to traverse a path $\sqrt{3}$ times the measured distance between outside and centre, which is not far from that expected if it has to pass round a series of cylinders. The permeability constant has to be defined, as there is no generally accepted formulation. For a cell in which the total concentration of the ion in question is static (that is, irrespective of whether the ions are labelled or not), the amount of ion entering per unit time equals the amount being lost, and we can write

$$P_oM_o = P_iM_i$$

for the equilibrium of total M, and

$$\frac{V}{S} \cdot \frac{dM_i^*}{dt} = P_oM_o^* - P_iM_i^*$$

for the rate of change of internal M^*, where V is cell volume, S is cell surface, and the suffixes i and o distinguish internal and external concentrations of the ion M, and an asterisk denotes labelled M. The P's are the two permeability constants.

Krogh[1] discussed P_i; but Conway[4] pointed out that P_o is the figure which measures the amount of M entering the cell per unit time and area, when the external concentration of M is unity. As the concentration can be measured in arbitrary units per unit volume, the result is that P_o expresses the amount entering the cell in terms of the quantity of M per unit volume in the solution; and if P_o is a true constant, the quantity entering the cell per unit time and area will be linearly related to the concentration of M in the external solution. We have found that this is the case in the physiological range of potassium and sodium concentrations, and P_o for sodium is about 0·0004 cm. hr.$^{-1}$ and for potassium about 0·0038 cm. hr.$^{-1}$.

A full description of the methods and results will appear later.

In vitro Effect of Penicillin on Prothrombin Activity of Bovine Plasma

Moldavsky, Hasselbrock and Caterno[1,2] have recently reported that both oral and intramuscular injections of penicillin consistently shorten the coagulation time of normal blood and produce a non-retractile clot. They also observed decreased bleeding-times in patients receiving penicillin. J. H. Lewis[3] investigated more thoroughly the effect of penicillin on blood coagulation in both normal and hæmophiliac subjects. *In vitro* tests indicated that oral and intramuscular administration of penicillin did not have any effect on the blood-coagulating mechanism in either, in spite of high plasma penicillin levels. His *in vitro* tests to determine the effect of penicillin at various concentrations on the coagulation time of normal and hæmophiliac blood showed no change on the coagulation time.

In view of the contradictory nature of such results and the clinical application of Moldavsky, Hasselbrock and Caterno's[1] finding ("the possible use of penicillin as a hæmostat and the danger of intramuscular clotting"), the influence of penicillin on prothrombin activity was investigated.

In vitro experiments conducted in this laboratory have shown that penicillin at a concentration of 3,400 units and more increases the prothrombin time of bovine blood plasma, while concentrations lower than this appear to decrease the prothrombin time. The effect of penicillin at lower concentrations is not, however, very significant. Further work is in progress. The result of a typical experiment is given in the accompanying table.

Incubation at 37° C. for 2 hours

Final concentration of penicillin (Oxford units) in the total volume of the mixture (1·4 c.c.) containing 0·4 c.c. of bovine plasma	Prothrombin time (in sec.) of 0·5 c.c. of resultant mixture
19,500	120
10,200	70
3,400	42
1,700	34
425	30
106	30
Control 0·4 c.c. plasma plus 1·0 c.c. distilled water	37

Symbiotic Micro-organisms of Aphids and Fixation of Atmospheric Nitrogen

MANY insects have associated with them specific micro-organisms, often present in special organs, which are passed on from generation to generation. Their function is in most cases unknown. In many instances where it has been possible to rear sterile insects lacking their symbionts, these have been stunted in growth and deformed, in other cases such insects have been found to develop in an apparently perfectly normal manner[1]. Fraenkel and Blewett[2] have shown that the poor growth of sterile larvæ of certain beetles, without their usual symbionts, may be restored to normal by the addition of certain factors of the vitamin B complex. In this case the role of the symbionts appears to be to provide the insect with these substances. It has been suggested from time to time, and more recently by Toth, that the symbionts are in many cases capable of assimilating gaseous nitrogen from the atmosphere. In his monograph[3], Toth concludes that a large number of insect species, including aphids, are able to fix nitrogen with the aid of their symbionts.

The direct experimental evidence for this conclusion rests on what is called 'the surviving system technique'. In this technique, aphids are ground up in a nutrient solution containing glucose and oxaloacetate, incubated at a suitable temperature and pH, and the increase in nitrogen content of the system (assumed to be due to fixation by the symbionts) measured by micro-Kjeldahl analysis. Following Toth's procedure exactly, I have measured the changes in total nitrogen content of such 'surviving systems' produced by grinding young individuals from actively multiplying colonies of either *Myzus persicæ* or *Doralis fabæ* in a nutrient medium ($MgSO_4$, 1 gm.; Na_2CO_3, 1 gm.; glucose, 5 gm.; oxaloacetic acid, 1·3 gm.; $CaCO_3$, 2 gm.; in $M/20$ phosphate buffer, pH 7, to 1 litre). These cultures were incubated, with shaking, either at 15° C. or 24° C. In all cases no increase in nitrogen content was observed—occasionally nitrogen was lost. Such cultures are by no means sterile, and the nitrogen gains observed by Toth might equally well be ascribed either to the symbionts or to contaminant micro-organisms.

A further series of experiments was carried out in which young feeding colonies of *Myzus persicæ* or *Doralis fabæ* were left in an atmosphere of oxygen and nitrogen containing 31·5 per cent of the stable isotope nitrogen-15. After 20–64 hr. the insect material, together with leaf material controls, was assayed for nitrogen-15. No uptake of nitrogen-15 by the insects could be detected. An uptake of nitrogen gas equal to 0·03 per cent of the total nitrogen content of the insects would easily have been observed. It is apparent that the aphids used in these experiments showed no trace of nitrogen-fixing activity.

The question remains whether, in view of their high rate of proliferation, aphids can obtain enough nitrogenous foods from the plant to balance their nitrogen economy. After considering the ratios of protein to carbohydrate in aphid food and excreta, Toth[3] considers this is not possible. He quotes the following figures of the composition of the solid material taken in and of that excreted.

	Protein (per cent)	Carbohydrate (per cent)
Food	1–2–(5)	90
Excreta	3·5	93

However, if Maskell and Mason's[4] figures for the amounts of nitrogen and carbohydrate in the sieve tubes of cotton plants are representative, the amount of nitrogen taken in must be much higher. They found such sieve tubes to contain 1 gm. nitrogen/100 ml. water and 5·95 gm. carbohydrate/100 ml. (ratio $\frac{\text{total nitrogen}}{\text{carbohydrate}} = 16 \cdot 8$ per cent). Furthermore, to compute the nitrogen balance of the insects, it is also necessary to know their rates of feeding and of proliferation. By following the increase in weight of single aphids (*Myzus persicæ*), Lea, Markham and K. M. Smith (unpublished) found the rate of uptake of food by a single aphid feeding on tobacco leaves to vary between 9 μgm. and 35 μgm./hr., with a mean of 25. Assuming the density of the food solution to be 1, and using the data of Maskell and Mason, it is seen (taking the mean rate of food uptake) that this corresponds to an uptake of combined nitrogen from the phloem of at least 0·25 μgm./hr. The total nitrogen content of an aphid is about 14·5 μgm. These aphids would thus double their nitrogen content in 58 hr. They were producing few offspring, and this doubling period falls well within the wide variability in rates of aphid multiplication. (Nitrogen lost by excretion has been neglected in this calculation, as it would appear to be negligible compared with that taken in.) It is interesting to note here that more than a hundred years ago Boussingault[5], from measurements of nitrogen contents of food and excreta of a cow, a horse and a turtle-dove, concluded that these animals do not fix nitrogen.

Finally, the mere fact that Peklo[6], from a study of the morphology of the symbiotic micro-organisms of aphids, places these in the *Azotobacter* group, gives no direct evidence that they are capable of fixing nitrogen.

From the above experiments the conclusion must be drawn that aphids do not take up nitrogen from the air. I wish to thank Dr. A. S. McFarlane for supplying the nitrogen-15, and Dr. Bentley, of the National Institute for Medical Research, for carrying out the nitrogen-15 assays.

Activation of Unfertilized Sea Urchin Eggs by Trypsin

PREVIOUS workers[1,2] have reported that commercial trypsin, crystalline trypsin and chymotrypsin are all able to activate the nuclei of unfertilized sea urchin eggs. The elevation of fertilization membranes has also been reported after treatment with low concentrations of crystalline trypsin[1]. In unfertilized *Pomatoceros* eggs, crystalline trypsin and chymotrypsin cause the formation of typical fertilization cones, but do not activate the nuclei[3].

As it is of interest to know to what extent the cytoplasm and the surface of the egg are involved in the parthenogenetic activation of sea urchin eggs by proteolytic enzymes, a reinvestigation of the whole subject has been undertaken, and a preliminary account of the results is given below.

The experiments described have been carried out on the eggs of *Psammechinus microtuberculatus* (Blv.). A 0·5 per cent solution of undialysed commercial trypsin (Kahlbaum) at pH 7·8–8·0 produced nuclear changes in 50–100 per cent of these eggs after two to four hours. The extent to which the nuclei were activated showed some variation, due, no doubt, to variations in the maturity of the eggs, taken from various females. The effect of the trypsin on the nuclei was to make them become enlarged but still with a distinct nuclear membrane. In some eggs this was followed by disintegration of the nuclear membranes and monaster formation. Within this space of time nuclear division rarely took place. After 5–8 hours irregular cleavage occurred in up to 60 per cent of the eggs.

When placed in hypertonic salt solution (0·6 c.c. of 2·5 *N* sodium chloride to 2 c.c. of egg suspension) the trypsin-treated eggs containing activated nuclei became spherical with smooth surfaces, as occurs in freshly fertilized eggs after similar treatment and in contrast to the wrinkled surfaces of unfertilized and unactivated eggs. This must indicate changes in the cortical layers of the eggs[4,5]. Angular plasmolysis, the characteristic response of older fertilized eggs to this treatment, did not occur.

After 4–6 hours there was found on the surface of trypsin-treated eggs a thin layer, presumably of extruded cortical material. During normal fertilization, cortical material is extruded and participates in the formation of the fertilization membrane (cf. ref. 2). The layer of extruded material may indicate a slight activation of the egg surface in the direction of the formation of a fertilization membrane; but a fertilization membrane cannot be formed as the vitelline membrane, which forms the basis of the fertilization membrane, is digested by trypsin of this strength[6].

The hyaline layer, which is differentiated after normal fertilization, is broken down rapidly in trypsin solution, and when fertilization occurs in the presence of trypsin the hyaline layer is not formed[6]. It is unlikely, therefore, that the layer of extruded material has any affinities with the hyaline layer.

Experiments with crystalline trypsin and chymotrypsin gave no activation of the nuclei or of the surfaces of the *Psammechinus* eggs, and thus the results of previous workers have not been confirmed, at least in respect to this species.

The results with commercial trypsin show that activation is more comprehensive than was formerly thought, the activation involving the surface of the eggs as well as the nucleus. The destruction of the surface layers of the egg by the trypsin prevents, however, the possible expression of the surface phenomena associated with normal fertilization.

The negative results with crystalline trypsin and chymotrypsin indicate that the activating substance in commercial trypsin may be neither trypsin nor chymotrypsin, as was formerly supposed.

Soil Phosphate Uptake as Influenced by Phosphatic Fertilizer

PERENNIAL rye-grass was sown in small pots (12 cm. in diameter) on August 3, and harvested on October 22, 1947. Seven plants per pot were grown, and six replicate pots per treatment were provided. Two top soils from North Auckland Province, both very poor in available phosphate, were used. The Maunu loam derived from basalt is akin to a lateritic type; the Wharekohe silt loam, derived from an early tertiary claystone, is a mature podsol. They are classified respectively as "immature red brown loam" and "strongly podsolized yellow earth" by the New Zealand Soil Survey. Primary calcium phosphate labelled with radioactive phosphorus was used as fertilizer in amounts equivalent to 100 mgm. P_2O_5 per pot, this being roughly equal to a rate of 100 kgm. P_2O_5 per hectare, calculated on an area basis. Dry-matter yields, total phosphorus and radioactivity were determined in the harvested plants.

The accompanying table gives some of the results obtained, the figures referring to sums of six replicates (pots). A full account will be published elsewhere.

	Maunu loam		Wharekohe silt loam	
1 per cent citric acid soluble P_2O_5 per cent	0·009		0·001	
P_2O_5 added (mgm.)	0	600	0	600
Yields (tops and roots) in gm.	0·61	8·56	0·84	13·24
P_2O_5 taken up by plants (mgm.)				
From fertilizer	0	37·2	0	95·5
From soil	1·1	3·3	1·65	14·5
Total	1·1	40·5	1·65	110·0

Thus plants that received the phosphatic fertilizer took up three to eight times as much P_2O_5 from the original soil phosphate as the controls.

This experiment was finished when there came to hand a paper by Spinks and Barber[1], who, using a radioactive tracer technique, obtained similar results with wheat. The occurrence of this phenomenon can thus be accepted as well established.

To my knowledge, the first hint that phosphate fertilizer might in some circumstances stimulate the uptake of phosphorus from the soil came from Leopold Zaleski[2] (the paper appeared probably in the twenties, but unfortunately at the moment I am not able to give a more exact reference). In his experiments small doses of superphosphate placed beneath oat seeds increased the phosphorus uptake by more than the amount of phosphorus contained in these small doses, thus giving an apparent rerecovery or utilization of more than 100 per cent. Without a tracer technique, however, it would not have been possible to prove a stimulating effect of this kind in conditions less definite than those of Zaleski's experiment.

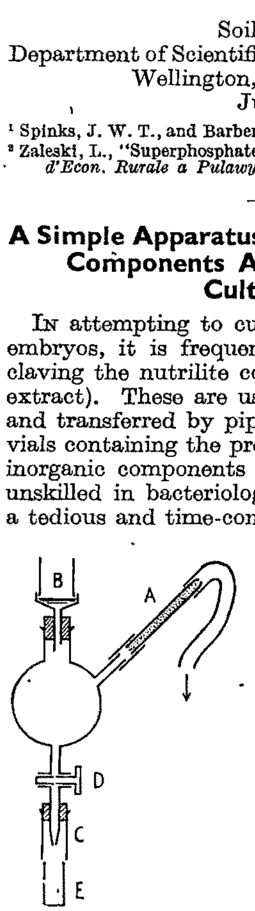
A Simple Apparatus for Adding Seitz-Filtered Components Aseptically to Embryo Culture Media

IN attempting to culture excised immature plant embryos, it is frequently desirable to avoid autoclaving the nutrilite components (for example, malt extract). These are usually Seitz-filtered separately and transferred by pipette to the individual culture vials containing the previously autoclaved sugar and inorganic components of the medium. To workers unskilled in bacteriological methods, this represents a tedious and time-consuming operation.



(*A*) Bacterial trap; (*B*) Seitz filter; (*C*) glass shield; (*D*) stop-cock; (*E*) culture vial

The apparatus illustrated is simpler to handle and satisfactorily avoids contamination. Essentially it consists of a separatory type funnel with side vent to which can be attached a simple bacterial trap *A*, namely, a glass tube with one end partially closed, filled with loosely packed cotton-wool. The apparatus is autoclaved before use, the apertures at *B* and *C* being plugged with cotton-wool, and the stop-cock *D* closed. During filtration, suction is applied through *A*, the partially sealed orifice preventing withdrawal of the contents of the trap. After filtration, the shield *C* is unplugged and the requisite number of drops (previously calibrated) added to the culture vials through the stop-cock *D*. The diameter of the shield should be slightly greater than the diameter of the culture vials *E*, which can then be inserted as illustrated while the filtrate is added. The bacterial trap *A* allows air to pass into the apparatus without contaminating the filtrate as the latter is withdrawn.

Correlation Between Lewis Blood Group and Secretor Character in Man

A NEW blood group character, designated as 'Lewis', was first described by Mourant[1], who found that the blood of 25 per cent of English people contained the Lewis factor, and that this group character is independent serologically of the *ABO*, *MN*, *Rh*, *P*, Lutheran and Kell systems. Somewhat later, Andresen[2] described 'anti-L sera' which are now known to be anti-Lewis sera. These sera agglutinated the red cells of 21 per cent of adult Danes and the cells of about 70 per cent of Danish children less than seven months old. Andresen put forward the view that the Lewis blood group was inherited by means of two allelomorphic genes L and l, the three possible genotypes being LL, Ll and ll. The data observed indicated that anti-Lewis serum agglutinates the red cells of adults if they are of genotype LL only, whereas in young children the genotype Ll is also detectable.

I have observed that the Lewis blood group character is intimately correlated with the secretor–non-secretor status within the *ABO* classification, Lewis-positive adult persons being non-secretors. This statement is based on the results obtained in the determination of the secretor type of twenty Lewis-positive and forty-two Lewis-negative persons. The twenty Lewis-positive persons were all non-secretors. Of the Lewis-negatives, forty-one were secretors and one (group A_1) was a non-secretor. On the basis of probability, it would appear that this result cannot be attributed to chance. In this sample the proportion of non-secretors is somewhat in excess of that found in the general population; there has, indeed, been a deliberate selection of Lewis-positive persons.

The classification of persons as secretors or non-secretors for the *A*, *B* and the so-called *O* factors was made by agglutination inhibition tests, using freshly collected and boiled saliva as inhibiting agent. The salivas from persons of group *A* (6 Lewis-positive, 19 Lewis-negative), *B* (1 Lewis-positive, 2 Lewis-negative) and *AB* (1 Lewis-positive, 2 Lewis-negative) were tested for inhibition of α- and β-agglutinins respectively. The salivas from persons of group *O* (12 Lewis-positive and 19 Lewis-negative) were examined with the following 'anti-*O*-sera': (1) Serum from a rabbit immunized with blood group substance obtained and purified from ovarian cysts of secretors of group *O*[3]. (2) A selected specimen of serum from the eel *Anguilla vulgaris*[4,5]. (3) Serum from a chicken immunized with suspensions of *Shigella Shigœ*[5]. Group *O* erythrocytes believed to represent the genotypes LL, Ll and ll of Andresen were agglutinated to the same titre by these sera.

Preliminary observations show that the salivas of Lewis-positive persons (non-secretors of the *A*, *B* and *H* substances) may inhibit the action of a strongly agglutinating dose of anti-Lewis serum at a dilution of 1 : 100 or more. The salivas of most Lewis-negative persons, possibly heterozygotes, show some power of inhibiting the action of Lewis agglutinins. Other salivas from Lewis-negative persons do not neutralize anti-Lewis serum.

Witebsky and Klendshoj[6] observed that the water-soluble substances in the secretions of those persons, classified as non-secretors owing to their inability to secrete the *A*, *B* or '*O*' (now called *H*)[7] substances, were nevertheless similar in general chemical properties to the *A*, *B* and *O* substances. A mucoid material possessing chemical characters common to the group substances and isolated from pseudomucinous ovarian cyst fluids obtained from secretors and non-secretors has been examined. The material inhibits completely and at high dilutions the action of two to three strongly agglutinating doses of anti-Lewis serum on Lewis-positive *O* cells[8]. Investigations in this field are being continued.

I wish to convey my sincere thanks to Dr. W. T. J. Morgan, Dr. R. R. Race, Miss Ruth Sanger and Dr. A. E. Mourant for their valuable advice and help.

Equations of Piezoelectricity

RECENTLY, Dr. Richard K. Cook[1] has criticized as errors certain equations in my book[2] in which mixed units occur. In particular, he points to my Eq. (1), which expresses the energy stored in a crystal upon which an arbitrary mechanical strain and an arbitrary electric field are impressed. His assertion that "the reader is therefore obliged to examine closely the origin of the formulæ he uses" would be more convincing if he had cited instances in which an incorrect conclusion has been drawn from Eq. (1). This equation is:

$$\xi = \tfrac{1}{2}\sum_{h}^{6}\sum_{i}^{6} c_{hi}S_hS_i + \tfrac{1}{2}\sum_{k}^{3}\sum_{m}^{3} \eta''_{km}E_kE_m + \sum_{m}^{3}\sum_{h}^{6} e_{mh}E_mS_h + \tfrac{1}{2}\frac{J\rho C\theta^2}{T} + \theta\sum_{h}^{6} q_hS_h + \theta\sum_{m}^{3} p_mE_m,$$

where the *c*'s are elastic constants at constant field, the *S*'s are strain-components, η'' is the dielectric susceptibility of the clamped crystal, *E* the field-strength, *e* a piezo-electric stress-constant, *J* is the mechanical equivalent of heat in ergs per calorie, ρ is the density, *C* the specific heat in cal.gm.$^{-1}$ deg.$^{-1}$, *T* the absolute temperature, $\theta = \Delta T$ is a small change in temperature, *q* is a thermo-elastic constant, and *p* a pyro-electric constant.

Dr. Cook's objection is to the use, in the same equation, of the co-ordinate *S* along with *E*, which may be regarded as a generalized force.

It should be recalled that mixed units occur in some of the classical equations in thermodynamics. In piezo-electric theory, following the method of thermodynamics, they were used by Voigt, for example, on p. 816 of his "Lehrbuch der Kristallphysik"; they occur in the treatment of electro-elastic phenomena by Born, and in such handbooks as that of Geiger and Scheel and the "Encyclopädie der mathematischen Wissenschaften". There is therefore nothing novel in the use of mixed units in certain energy equations. It is true that in interpreting the derivatives of my Eq. (1) it is necessary —as was also the case with Voigt—to distinguish carefully between internal and externally impressed stresses; the same may be said of my Eqs. (243) and (243*a*). Equations (1), (243) and (243*a*), although thermodynamically correct, are not such that their derivatives lead immediately to the desired results. Nevertheless, the relations between mechanical and electrical quantities, in the commonly accepted form of coupling equations with stresses applied externally, are obtained by appropriate treatment of these derivatives, as may be seen by inspection of my Eqs. (186), (246), (248*a*) and (250).

On page 246 of my book are four equations analogous to the expressions for the internal energy U, the Helmholtz function A, the Gibbs function G, and the enthalpy H. Although the analogies are not exact, the equations were formulated as leading to the defining expressions for the piezo-electric coefficients.

More recently, I have undertaken the formulation of a set of equations in the form of exact differentials, such that, when integrated, the partial differentials lead directly to expressions for the coupling between thermal, mechanical and electrical quantities. It turns out that this can be done very simply by adding to the thermal and mechanical terms in the dU, dH, dA and dG functions, further terms expressing the electrical contribution to the energy. In the equations below, the field-strength E and polarization P are treated as generalized force and co-ordinate, respectively. Absolute temperature and entropy are denoted by Θ and σ, while the stress and strain matrices are denoted by T and S. With solids, $-T$ and S replace the pressure p and volume v that are used in the case of gases or vapours; here each component of T is considered as positive when it tends to produce a positive component of S. The equations are:

$$\begin{aligned} dU &= \Theta d\sigma + TdS + EdP \\ dH &= \Theta d\sigma - SdT + EdP \\ dA &= -\sigma d\Theta + TdS - PdE \\ dG &= -\sigma d\Theta - SdT - PdE \end{aligned}$$

From Maxwell's relations, and assuming (over a limited range) known linear relations between Θ and σ, between T and S, and between E and P, one can integrate and find equations for U, H, A and G. (The extension of the thermodynamic equations to include electrical parameters was developed independently by Prof. K. S. Van Dyke and discussed by him in "A Manual of Piezoelectric Data", Fifth Semi-Annual Report to U.S. Army Signal Corps, Part II, under Contract No. W28–003 sc–1556 with Wesleyan University, January 20, 1948. I am indebted to him, and also to Dr. J. S. Mendousse, for helpful suggestions.) The partial derivatives of these equations yield at once the usual equations for coupling, in which the externally applied stress and the actual field in the crystal are given directly. These coupling equations may be regarded as *equations of state*. The equation for dG leads to Eq. (2) in my book. The equations for dA, dU and dH lead, respectively, to modifications of my Eqs. (1), (243) and (243*a*).

It is easily shown that dA as expressed above is related to $d\xi$, as obtained from my Eq. (1), as follows:

$$d\xi = -dA + 2c^{E}SdS.$$

The fact that in using Eq. (1) a discrimination had to be made between internal and external piezoelectric stresses may be said to be due to the presence of the term $2c^{E}SdS$. If I had written Eq. (1) with the sign of the first term reversed, $d\xi$ would have been the same as $-dA$ and all stresses in the derivatives would have been external.

Equations similar to the foregoing may also be written, in which the polarization P is replaced by the displacement D.

Pulsating Stars and Nuclear Energy

THE explosion in an 'atom bomb' occurs when two masses of uranium-235, each too small to retain sufficient neutrons to start a chain reaction, are brought into juxtaposition within a certain critical volume. A similar state of affairs will account for the phenomena of pulsating stars, but with this difference, that whereas in terrestrial experiments the reacting material is dissipated by the force of the explosion, in the interior of a star those heavy nuclei which have escaped fission during the course of one explosion are reconcentrated by gravitational attraction and are available as a neutron source, or for fission, a few days later.

The data necessary for mathematical investigation have not yet been fully released, but it may be assumed that heavy nuclei will gravitate toward the centre of a star when convection currents and other types of instability have subsided. With the immeasurably larger quantities of available matter as compared with terrestrial standards, the critical conditions of explosion will be quite different. Instead of a few grams or kilograms of highly concentrated fissile material brought together into a critical volume measured in cubic centimetres, it is possible that neutron generation will exceed dissipation when the necessary minimum number of tons is concentrated into a space of thousands or millions of cubic kilometres. If the pressure of radiation engendered by nuclear fission is great enough to overcome the structural forces in the star, it will reach the surface and carry away with it a halo of gaseous material, and this is clearly seen in the case of a nova. If, however, the gravitational field and the opacity of the star are sufficient to withstand the pressure, the greater part of the explosion will be kept within the bounds of the star, and after a period of expansion and increased luminosity the star will collapse under its gravitational field, until the reactive materials have again been brought together in sufficient concentration to start another cycle.

Although mathematical proof is not yet available, this suggestion will account in general terms for the successive phases in the cycle of the Cepheid variables —the rapid expansion with little change of surface brightness, due to a wave of compression from within; the slower collapse under gravitational force, showing irregularities due to secondary waves; the quantitative relation between absolute magnitude and period; and the almost limitless supply of energy. In the case of supernovæ, quantitative considerations of the energy radiated support the belief that the origin of the energy is a nuclear chain reaction[1].

ADSORPTION BY MONTMORILLONITE, AND ITS RELATION TO SURFACE ADSORPTION

By DR. D. M. C. MACEWAN
Pedology Department, Rothamsted Experimental Station, Harpenden

THE nature of the forces giving rise to the intracrystalline swelling of montmorillonite has been several times discussed. The recent work of Bradley[1] and of myself[2,3,4] on the swelling caused by adsorption of organic liquids enables us to get a clearer view of the problem, because these liquids form well-defined complexes in which the influence of the exchangeable ions is less marked than with water.

The questions which have to be answered are: (*a*) Why do the organic molecules penetrate into the montmorillonite 'crystals'? (*b*) Why is the resulting expansion limited in extent? X-ray photographs show that the molecules between the structural sheets of the clay mineral are not in the form of a normal liquid, but are arranged in well-marked layers, reminiscent of the layer-structure which has been postulated for adsorbed films on the actual surface of crystals[5]. On this basis it may be suggested that one factor in the formation of these complexes is a repulsive force which comes into operation when crystalline surfaces are brought very close together in a liquid medium, due to their collecting layers of strongly adsorbed molecules[3]. In order to explain the observed equilibrium an attractive force must also be found.

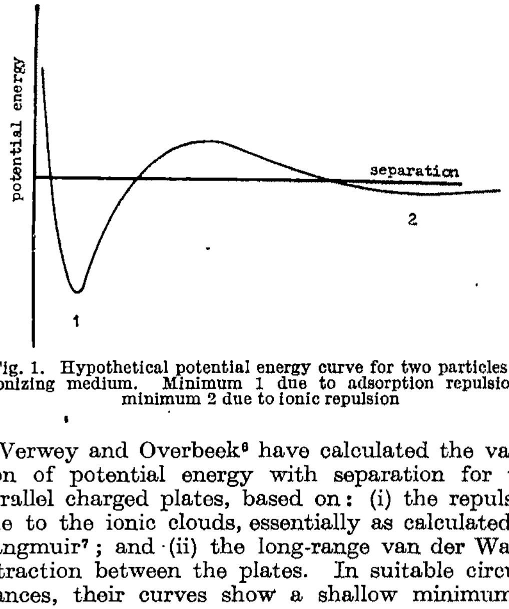

Fig. 1. Hypothetical potential energy curve for two particles in ionizing medium. Minimum 1 due to adsorption repulsion; minimum 2 due to ionic repulsion

Verwey and Overbeek[6] have calculated the variation of potential energy with separation for two parallel charged plates, based on: (i) the repulsion due to the ionic clouds, essentially as calculated by Langmuir[7]; and (ii) the long-range van der Waals' attraction between the plates. In suitable circumstances, their curves show a shallow minimum of potential energy at considerable distances of separation (50–500 A.), followed by a maximum and a monotonic decrease as the plates are brought closer together. If to the terms considered by Verwey and Overbeek we add a term corresponding to the free energy of adsorption of the superficial layers of molecules, we will get a further (rapidly dying out) repulsive contribution, and we might thus expect a second minimum in the total potential energy curve corresponding to separations of the order of a few molecular diameters (Fig. 1).

It is noteworthy that such a minimum has been postulated by Verwey and Overbeek[8] in order to explain the phenomenon of repeptization, and to get it they had to invoke the Born repulsion. The considerations given here suggest that a minimum may be obtained at separations which are quite large in comparison with those at which the Born repulsion will be able to act. Verwey and Overbeek's treatment, of course, was confined to lyophobic systems, and particle-solvent interactions were specifically excluded; but it is doubtful if the formation of adsorbed surface layers of molecules is confined to systems that would be described as 'lyophilic', and it may well be quite a general phenomenon.

When one attempts, however, to express the above ideas in quantitative form, certain difficulties appear. There are no adequate data on the change of surface-free energy with adsorption of organic liquids by montmorillonite, but Bangham and Mosallam's[5] careful measurements enable this quantity to be obtained for mica in contact with methanol, benzene and carbon tetrachloride; and in view of the close structural similarity of mica and montmorillonite[9], it does not seem unreasonable to suppose that these results will apply fairly well to montmorillonite also. The lowering of free energy for a given quantity of organic liquid adsorbed is given by Bangham's form of Gibbs' expression $RT\int\Gamma d\log p$, taken between the appropriate limits, and all the quantities here can be derived from Bangham and Mosallam's data. We need, of course, to know the value of Γ corresponding to one, two, . . . layers; and to calculate this I assumed (i) that the density of the adsorbed layers is the same as that of the normal liquid, and (ii) that the orientation and thickness of the adsorbed molecules are those given by direct X-ray spacing measurements on the montmorillonite complexes[4]. The general correctness of the assumptions is suggested by the fact that the completion of successive layers as thus determined corresponds in most cases with points of discontinuity in Bangham and Mosallam's adsorption isotherms.

In applying these results to the montmorillonite complexes, one must allow for the fact that, unlike the surface films on mica, they have no free liquid surface (by adding the free surface energy of the liquid). The final result for methanol is shown in Fig. 2, curve I, which gives the lowering of free energy per unit cell as a function of the separation of the montmorillonite sheets, the value for no separation being arbitrarily set equal to zero. On the same graph is shown the potential energy variation due to van der Waals' attraction, as calculated from Verwey and Overbeek's formula[10] with $A = 10^{-12}$ (curve II). Clearly this energy is far too small in comparison with the adsorption energy to give a position of equilibrium at any suitable distance. The assumed value of A is likely to be too large rather than too small, so the van der Waals' force cannot account for the observed equilibrium unless the adsorption energy is seriously in error, which seems unlikely. There must therefore be another type of attractive force at short separations.

The possibility of this force being electrostatic in origin is worth considering. At larger separations, of course, the net force due to the ions is repulsive, and the treatment of Langmuir[7] essentially applies. But here we are dealing with the case where not only the Gouy, but also the Stern layers may overlap, and the essential assumption underlying the application of the Poisson–Boltzmann equation, that each ion moves in the mean potential field of all the ions, may break down. The ions will then rearrange themselves in a single layer, so that each one occupies a certain 'cell', bounded on either side by the two interacting surfaces, from which other ions are excluded. The force between the sheets will then be attractive, and its potential will increase uniformly with separation, at a rate depending on the dielectric constant of the medium. Assuming this is the same as for *solid* methanol, we get curve III in Fig. 2, and combining it with the curve of adsorption free energy we get curve IV, showing a stable position with two layers of methanol molecules between the montmorillonite sheets, which is what is actually found.

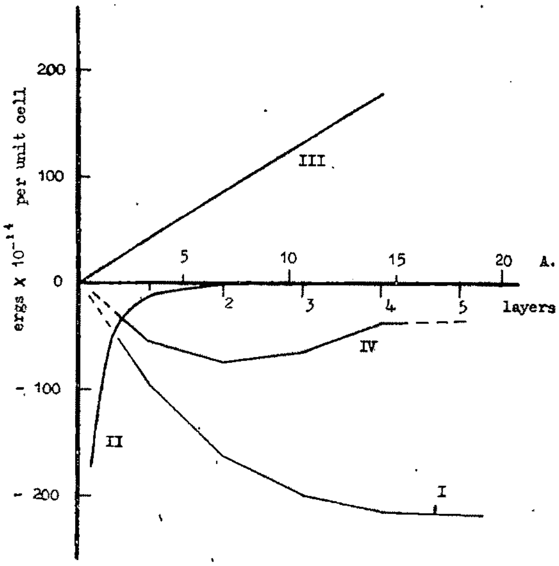

Fig. 2

The electrostatic force, unlike the van der Waals' force, is thus of the right order of magnitude to explain the observed effect. Its actual value is subject to error, because no account has been taken of the effect of segregation of the cations towards one or other of the two sheets. With 'bare' cations, this effect should lead to a considerable lowering of the attractive force at 10 A. separation. It is probable, however, that the cations will co-ordinate polar groups (or residual water molecules) in such a way as to increase their effective size, and make this effect less marked. At separations greater than about 10 A., such segregation is bound to set in, reducing the attractive force, until finally, with the attainment of the normal Gouy layer distribution, the force becomes repulsive. Actual values for the separation in organic complexes[4] vary up to about 11 A. The case of adsorption of large complex ions, for example as studied by Gieseking[11], is, of course, quite a different one.

I am grateful to Dr. D. H. Bangham, Dr. S. Levine and Dr. R. K. Schofield for conversations on the subject of this communication, but they are not responsible for the opinions expressed in it.

HIGH VACUA

GLENEAGLES CONVENTION

ON October 12 and 13, the Society of Chemical Industry sponsored a convention on high vacua under the presidency of Sir Charles Darwin, director of the National Physical Laboratory. It is worthy of record that there was much appreciative comment at the choice of Gleneagles for the meeting, and the view was expressed widely that the so-called 'country house party' system in which interested persons meet in conditions of intimacy for a time with little or no distractions has much to recommend it.

The meetings opened with a brief historical survey and some personal recollections by Sir Charles Darwin. His remarks on the interaction of pure science and technological practice reminded his listeners that modern developments have produced a situation in which the contribution of the highly expert technician is now an essential to success. As he rightly remarked, it is no longer practicable for the physicist or the chemist in his research laboratory himself to make the apparatus he requires for his own use.

Dr. Saul Dushman, of Schenectady, dealt with the scientific aspects of vacuum technique. He referred to the advances resultant on the advent of the vacuum tungsten lamp and its developments, the magnetron, and fluorescent-screen cathode-ray tubes. The introduction of high-vacuum technique has enabled the production of high-energy accelerators such as the cyclotron, betatron and synchrotron. Many of the developments, the result of war-time demands, would astonish those concerned with these matters even ten years ago, he remarked, and it is fair to say that the technique has now emerged from the experimental stage to take its place as a valuable tool for the physicist. Oil-vapour pumps are available with speeds of exhaust ranging up to, and above, 7,000 litres/sec. (15,000 cu. ft./min.) and producing ultimate vacua ranging from 10^{-3} microns to 10^{-5} microns mercury pressure.

Dr. Dushman spoke of the difficulties of producing accurate gauges for such measurements; he believes that, in some cases at least, the limit of measurement has, for the time being, been reached.

Dr. J. C. Swallow and Dr. J. S. Gourlay, of Welwyn, discussed the applications of high vacua in the paint and plastics industries. The first part of their paper dealt with the technique of metallization now becoming increasingly important on a large scale. This technique involves the deposition *in vacua* of a thin partially transparent layer of metal over a surface.

The metal is evaporated from a small source so placed that it impinges on the surface at an oblique angle. Irregularities on the surface produce local variations in the thickness of the metal layer, and the shadows cast by these enable their heights to be calculated. A very interesting process has also been developed for coating polymethyl methacrylate with aluminium. This is used to make the spherical plastic mirrors of diameters from 3 in. to 11 in. used in television projection.

In high-vacuum distillation it is hoped that the progress recently made will soon permit the separation of the various molecular species in a pure state. In plastics, short-path distillation can now be employed in the manufacture of a high molecular weight plasticizer by removing the ester from the reaction before its completion, which would require such high temperatures as to cause discoloration. In general, in a reaction $A + B = C + D$, the procedure is to remove by high-vacuum distillation C or D, and the technical requirement of purer and still purer plasticizers of high molecular weight may well lead to the adoption of this procedure.

An interesting suggestion by Dr. Swallow was to consider not only the use of high-vacuum technique in the production of plastics, but also the use of plastics in high-vacuum apparatus, particularly for gaskets, inspection windows, and sheathing.

Dr. R. S. Morse, of Cambridge, Mass., contributed two papers on high-vacuum dehydration and distillation. An exciting feature of his papers was the evidence of applying highly complex processes to the production of very large quantities of materials like penicillin, sera, and the like. The cold-trap vapour pumping system in which air pressure is reduced to less than 50 microns of mercury with a mechanical pump is now in use on a large scale for drying biological preparations. For the production of penicillin and streptomycin, however, diffusion pumps are used to reduce the free-air pressure to 1–10 microns. The vapour is condensed and continuously removed as ice by rotating scraper blades. In an effort to eliminate all mechanical problems and convert a desiccant system to a continuous operation, continuous liquid chemical absorption processes are being studied. In these, free air is removed to 10–100 microns and vapour is continuously absorbed with a hygroscopic medium. The medium is afterwards reconcentrated and, at reduced temperature, again circulated and additional water vapour removed. There are particular and unique problems involved in designing high-vacuum drier equipment, such as the heat transfer to the product. Efforts have been made also to reduce the drying time to a minimum, and Dr. Morse suggested that the time is approaching when high-vacuum drying operations will compete with more usual procedures such as spray drying.

Dr. E. W. M. Fawcett, of the Paint Research Station, discussed the application of high-vacuum distillation to the processing of triglyceride oils. Molecular distillation is limited generally to distillands in the molecular weight range 300–1,200; it has a poor fractionating power and is rather high in cost. The rapid development of solvent fractionation processes may well also limit the application of the distillation process in some directions. It would appear, said Dr. Fawcett, that molecular distillation is a process for the special case, such as the recovery of vitamin A from fish liver oils, and, in his view, it is unlikely to be applied generally on a commercial scale. In contradistinction to its rather limited scope in commercial-scale practice, however, molecular distillation as a laboratory process has great possibilities and will undoubtedly find increasing usage with the perfection of the necessary high-vacuum technique.

Mr. R. A. Stauffer, of Cambridge, Mass., spoke on vacuum metallurgy, where much of the interest is still in the research and development stage. The two major advantages of processing metals *in vacuo* are that metals so processed are protected from reaction with gases, and those metallurgical reactions in which gaseous products are formed from solid or liquid reactants are favoured by maintaining a low gas pressure over the reactants. During the War very large quantities of magnesium were produced in Canada and the United States using a high-vacuum technique, but most of the plants are now closed because of high operating costs and poor plant locations. It is probable, said Mr. Stauffer, that lithium metal will be produced in the near future using vacuum techniques, and the production of other metals of the alkali and alkaline earth metal group have been studied, but so far only on a small scale. Small quantities of barium and cæsium are being made but the amount is limited to a few tons per year.

It is theoretically possible to drive reactions involving dissociation of metallic compounds which give rise to gaseous by-products; but in practice the number of metals which might be prepared by those techniques is extremely limited. Many of the halides can be dissociated by heating to high temperatures, but these reactions cannot be readily driven by vacuum techniques since most of the halides are quite volatile themselves and are removed, along with the halogen formed, as a by-product. A promising application for vacuum vaporization is in conjunction with the 'Kroll' process whereby titanium chloride is reduced with magnesium, forming a mixture of titanium, magnesium, and magnesium chloride from which titanium must be recovered. A vacuum-vaporization technique is used for removal of magnesium and magnesium chloride in order to avoid a leaching operation which would contaminate the titanium.

Vacuum technology as applied to the design and construction of vacuum furnaces is progressing rapidly and new techniques for melting are being developed. There appears, however, to be little to be gained in the mechanical properties of metals by vacuum heat-treating operations.

Mr. Stauffer concluded by saying that the advantages to be gained by the use of vacuum technology have not been fully evaluated and in some cases the equipment required for its industrial application to metallurgical processes is not fully developed.

The final session was devoted to two papers, one by Dr. C. R. Burch, of Bristol, who spoke of developments arising out of experiments on vacuum distillation, considered as an illustration of the impact of one technology on another; and the other was by Prof. M. L. E. Oliphant, of Birmingham, who spoke of high vacua in nuclear physics, mentioning in particular some of the practical difficulties of work in this field. Dr. Burch's talk was largely historical for, as he explained, he has not worked on the subject for some years.

Prof. R. V. Jones, of Aberdeen, in his concluding remarks, directed attention to some of the main points made by the speakers and in the discussions. The convention concluded with an expression of thanks to those who had made it possible.

BEHAVIOUR OF PIGS

IN the course of experimental work of a nutritional and physiological character at the National Institute for Research in Dairying, R. Braude has noted some interesting features about the behaviour of pigs (*Bull. Animal Behaviour*, No. 6; January 1948). These observations have been recorded without any attempt to fit them into the framework of existing theories of behaviour, and, in the words of Dr. E. S. Russell, they merely "serve to illustrate what is the most characteristic feature of behaviour, namely, that the animal tries or strives to do something specific, that it seems to achieve some end, to satisfy some need".

On one occasion a wooden block resembling a sow with two rows of rubber teats fitted at the approximate spot was put into the farrowing pen. It was placed as near as possible to a sow which was farrowing. Not one of the fourteen piglets born on this occasion showed any interest whatsoever in the dummy teats, while all were keenly interested in the real teats, and as usual fought for access to them.

Another observation concerns the behaviour of piglets in suckling usually from the same teat. Donald has stated that "this ability must be founded mainly on sight, with some capacity to recognize the feel of a nipple playing a secondary part. Hearing may be disregarded, and so may a sense of smell, for pigs placed with a foster mother will, if they are able, take up the position they had on their original mother." From the start it seems to be of importance to the piglets to obtain a correct position on the udder. The quality of the teats varies to such an extent that it is not surprising that in the early stages of suckling the piglets are prepared to fight for access to the good ones and those successful occupy them permanently. The resultant growth-rate of the victors indicates the importance of this selection. With a small litter the best teats are soon discovered and continue to be sucked throughout lactation, while the poor ones are completely abandoned, and gradually dry off. With large litters some of the piglets never secure the chance of settling down at a good teat, and this fact seems to be mainly responsible for the usual one or two 'runts' in a large litter.

The effects of massaging the udder by the piglets just before the actual suckling have also been observed. With cows, the composition of the milk obtained depends on whether the udder has been previously stimulated or not, while in pigs there is evidence that the milk obtained by draining it off is only half as rich in fat as that obtained by the young pigs suckling. That the controlling factor is of a hormonal nature has been confirmed by Kon, Thompson and Braude, and by means of 'Pitocin', a proprietary extract from the posterior lobe of the pituitary which contains the oxytocic principle, it is now possible to milk a sow in much the same way as a cow. To milk the sow after treatment with 'Pitocin' the sow has to be roped. Here an interesting aspect of behaviour is shown. It is well known that a sow will struggle against roping and that once caught she will try to get rid of the rope. What she usually does, however, is to pull back with all her strength, and by so doing makes the noose only more secure. On the other hand, if she were to walk forward—and there is nothing to stop her doing so—the effectiveness of roping would be completely lost. For some unknown reason this never occurs. The explanation that she can see the holder of the rope in front of her and tries to back away from him has proved to be untrue. The holder of the rope has been concealed and two people have been placed behind the sow. Those behind have had to push with all their strength to make the sow step forward.

Other observations show that, once a sow has done a long walk to the piggery where the boar is kept, she seems to learn the route and needs little guiding on subsequent occasions. Sows usually keep to the road and are careful when leaving it, making sure that the path they are taking is safe for them.

Except when mating, two grown pigs brought together will fight each other until one establishes a complete supremacy; sometimes even death may result. Mixing young weaners from different litters invariably results in a fight; but these soon settle down together. On the whole, however, pigs like company, and cases have been known when separated pigs have had to be brought back to their mates because "they went in seclusion on what amounted to a hunger strike". It is also known that a strong pig will keep a weaker one away from the food trough, while in the pen the favourite place for sleeping is occupied by the stronger. On occasions when two lots of pigs are mixed together in one pen, the usual fight is followed by the relegation of the defeated to the dunging passage.

That pigs quickly become accustomed to new routines which have to be introduced into an experimental piggery is shown by the following. Pigs have to be weighed at frequent intervals, sometimes daily and at least once weekly. At first it is difficult to get them into the weighing pen; but, after a few times, they walk into it of their own accord as soon as the door of the weighing pen is opened. A clearer example of a conditioned reflex is quoted by Braude from Denmark. There, a certain pigman arrives at his piggery in the morning and, as his first job, rings a heavy bell. This was a signal for all the pigs in that piggery to get up and go out into the dunging passage to defecate and urinate. The procedure was repeated as regularly in the afternoon, and this practice kept the piggery clean.

Information on the feeding habits of pigs has also been collected and shows the pig is a selective feeder. The now well-known story of its liking for copper is re-told, together with further evidence which has been collected by experimental inquiry.

NATURE AND CONSTITUTION OF GLASS

AT the recent joint meeting of the International Commission on Glass and the Society of Glass Technology, a symposium was arranged having as a general title "Some Aspects of the Nature and Constitution of Glass". Fifteen papers, presented by American, British and Continental investigators, ranged widely over the subject and raised, in each of three sessions, lively and sustained discussions.

In an introduction to the series of papers, Prof. W. E. S. Turner reviewed the important historical developments of the subject and referred to the place of theory in glass technology. Whereas for some forty years or more Tammann's theory of glass as a supercooled liquid had done much to account for many of the properties of glasses, greater insistence was now being laid, as indicated in the paper "Solid

Liquids" submitted by Dr. F. W. Preston (Butler, U.S.A.), on the elasticity and therefore solid character of glass, with a definite atomic structure like a crystalline material, although without the regular repetition of the structural units found in a crystal.

Mr. S. M. Cox (Sunderland), in his paper on "An Elementary Kinetic Theory of Dilute Silica Glass", developed further a kinetic theory he had previously outlined. He employed an ingenious short film to illustrate the movements of the atoms at different temperatures and to explain his concepts. He suggested that an important term in equations describing the variation of physical properties with temperature is the proportion of loosely linked oxygen atoms, and he showed that the equation for this proportion can be derived from a simple distribution of potential energy curves. Equations relating the electrical conductivity with temperature, and of viscosity with temperature, were derived, and it was shown that the calculated results compare favourably with known experimental data.

Dr. G. O. Jones (Oxford) stressed the view that the study of glass can make a great contribution to the theory of the liquid state and the theory of melting. He outlined the present state of knowledge of the property-temperature changes in the transformation range and indicated the need for experimental work designed to provide full thermodynamic data. He also emphasized the need for experimental work on the kinetics of the crystallization process in glasses, on the stabilization phenomena, on the chemical durability of very thin films, and on the need for a theory of viscosity which would include the delayed elasticity effect. In the discussion, Prof. A. Smekal (Darmstadt) referred to work in Germany during the last eight years, particularly to the electron microscope examination of fracture surfaces, and to substances which have their transformation ranges near the melting point.

Mr. J. E. Stanworth (Sheffield) reviewed recent ideas of glass from the point of view of their ionic structures, referring particularly to the use of the electro-negativity values of the elements as a guide to their behaviour in a glass structure, and to the unusual behaviour of lead, bismuth and thallium, three ions which can be introduced in large percentages into glasses because of their high deformabilities.

Dr. J. M. Stevels (Eindhoven) discussed the relation between the dielectric losses and the constitution of glass, first describing briefly the theory of Gevers and du Pré, and the manner in which the theory explains the formulæ of Strutt and von Schweidler for the dependence of loss angle on temperature and frequency, respectively. Dr. Stevels pointed out the need for measurements at temperatures approaching absolute zero, and then outlined his theory of the effect of composition on losses, developing an equation which agrees with known data at a frequency of about 10^6 cycles per second.

Dr. S. P. Varma first presented a paper written in collaboration with Prof. W. A. Weyl (Pennsylvania State College), and also one by Dr. F. L. Jones and Dr. N. J. Kreidl (Rochester, N.Y.), both papers dealing with the optical properties in relation to constitution. Dr. Varma emphasized the fact that cations with electronic structure not of the noble gas type have bonding properties to neighbouring ions markedly different from corresponding noble gas-type ions. A series of curves showing molar refraction against composition, for silicate and borate glasses, emphasized the high contribution of lead ions as compared with barium and strontium ions, and of zinc ions as compared with magnesium ions.

A paper by Mr. J. B. Murgatroyd (Greenford) (read by Dr. E. J. Gooding) described the delayed elastic effect in glass fibres and showed that this effect increases with decrease in fibre diameter. Some conclusions were made concerning the arrangement of the bonds in fibres, and the relation between the structure of chilled and liquid glass.

Mr. R. W. Douglas (Wembley) outlined a theory of viscosity for simple glasses, based on the idea that there are two equilibrium positions (separated by an energy barrier) for each oxygen atom, the application of a stress enabling the oxygen atom to move from one potential minimum to the other; together with the thermal agitation of the atoms, this movement can provide flow. An equation for viscosity derived from this theory was used to compare calculated with known data, and the conclusion drawn that in complex glasses other atoms than the oxygens (for example, the sodium atoms) are probably involved in the flow mechanism.

Dr. G. O. Jones also spoke on the flow of glass, with particular reference to temperatures below the transformation range; he described the experimental results of strain-time measurements, and suggested that a model representing accurately the observed values could be either a number of Maxwell models in parallel or Voigt models in series, using a suitable distribution of relaxation times. In the discussion, Prof. A. Smekal referred to the measurements in Germany of the rate of crack propagation, using ultrasonics, and to theoretical work showing that the Griffith flaw theory can explain the continuous distribution of relaxation times and elastic after-effects.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, December 13

British Museum (Natural History) (at the Royal Scottish Museum, Chambers Street, Edinburgh), at 5.30 p.m.—Mr. Douglas A. Allan: "The Geology and Scenery of Scotland" (Swiney Lectures).* (Further Lectures will be given on December 15 and 17, January 17, 19, 21, 24, 26 and 28.)

Manchester Literary and Philosophical Society (in the Reynolds Hall, College of Technology, Manchester), at 5.30 p.m.—Dr. E. Lind: "Cheshire Meres".*

University of London (at the Institute of Education, Malet Street, London, W.C.1), at 5.30 p.m.—Mr. Corder Catchpool: "Education for International Understanding—Central Europe".*

Tuesday, December 14

Society of Chemical Industry, Plastics Group (at Gas Industry House, 1 Grosvenor Place, London, S.W.1), at 2.30 p.m.—Dr. D. D. Eley: "Biological Polymers". (Members of the Biochemical Society are invited.)

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.8), at 5 p.m.—Scientific Papers.

Institute of Physics, Electronics Group (at 47 Belgrave Square, London, S.W.1), at 5.30 p.m.—Dr. J. D. Craggs: "Some Limitations of Particle Counting with Electron Multipliers and Geiger Counters".

Institution of Electrical Engineers, Radio Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "Frequency Modulation versus Amplitude Modulation" (to be opened by Mr. H. L. Kirke).

Institution of Naval Architects (joint meeting with the Institute of Marine Engineers, at 85–88 The Minories, London, E.C.3), at 5.30 p.m.—Prof. L. C. Burrill: "Latest Developments in Reversible Propellers".

Illuminating Engineering Society (at the Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 6 p.m.—Dr. J. N. Aldington: "The Gas Arc—a New Light Source".

Institution of Structural Engineers, Lancashire and Cheshire Branch (at the College of Technology, Manchester), at 7 p.m.—Mr. R. A. Foulkes: "The Use of Light Alloys in Structures".

Society of Dyers and Colourists, Scottish Section (at the St. Enoch Hotel, Glasgow), at 7 p.m.—Mr. M. R. Fox: "The Relationship between the Chemical Constitution of Vat Dyes and their Dyeing and Fastness Behaviour".

Royal Institute of Chemistry (in the Material Research Laboratory, Philips Electrical, Ltd., New Road, Mitcham Junction), at 7.15 p.m.—Mr. R. J. Hercock: "The Theoretical Basis of Photography".

British Cultural Committee for Peace (at St. Pancras Town Hall, Euston Road, London, N.W.1), at 8 p.m.—Discussion on "Culture and Peace—with Reference to the Congress at Wroclaw" (to be opened by Prof. J. D. Bernal, F.R.S., Mr. Peter Blackman and Dr. Olaf Stapledon).

Wednesday, December 15

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 4.45 p.m.—Scientific Papers.

Royal Meteorological Society (joint meeting with the Royal Astronomical Society, in the Lecture Theatre, Science Museum, Exhibition Road, London, S.W.7), at 5 p.m.—Discussion on "Post-Glacial Climatic Change".

Institute of Welding, North London Branch (at East Ham Technical College, Barking Road, London, E.6), at 7.30 p.m.—Open Discussion on "Welding Methods".

Society for Visiting Scientists (at 5 Old Burlington Street, London, W.1), at 7.30 p.m.—Discussion on "Relations between Scientists and Administration" (to be opened by Mr. F. A. Cobb, M.P., Dr. R. Cockburn and Dr. C. Gordon.

Thursday, December 16

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. B. Katz: "The Electrical Properties of the Muscle Fibre Membrane"; Dr. M. F. Perutz: "An X-Ray Study of Horse Methæmoglobin", Part 2.

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. G. Szegö: "Recent Investigations on Electrostatic Capacity and related Quantities".

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.15 p.m.—Messrs. R. C. Trumbull, W. Hardiek and E. G. Lawford: "Notes on the Treatment of Pyrites Cinders at the Plant of the Pyrites Co., Inc., Wilmington, Delaware".

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 6 p.m.—Mr. J. B. Birks: "The Physical Applications of Microwaves".

Royal Aeronautical Society (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6 p.m.—Mr. D. J. Lyons: "Present Thoughts on the Use of Powered Flying Controls in Aircraft".

Textile Institute, London Section (at the Holborn Restaurant, 218 High Holborn, London, W.C.1), at 6.30 p.m.—Discussion on "Technical Education" (to be opened by Dr. J. C. Withers).

British Institute of Radiology (at 32 Welbeck Street, London, W.1), at 8 p.m.—Dr. Denis Taylor: "British Radiation Monitoring Equipment".

Friday, December 17

Institute of Navigation (with the Royal Geographical Society, at Kensington Gore, London, S.W.7), at 4.30 p.m.—Opening by H.R.H. the Duke of Edinburgh of an Exhibition "Navigation through the Ages": at 5.30 p.m.—Sir Robert Watson-Watt, F.R.S.: "Radio and Position". (The Exhibition will be open at 10,30 a.m. until January 31.)

Physical Society, Low-Temperature Group (in the Lecture Theatre, Science Museum, Exhibition Road, London, S.W.7), at 4.30 p.m.—Third Annual General Meeting; at 5 p.m.—Prof. D. M. Newitt, F.R.S.: "The Use of Thermodynamic Diagrams in Industry".

Physical Society, Optical Group (at the Institute of Physics, 47 Belgrave Square, London, S.W.1), at 5 p.m.—Scientific Papers.

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London, S.W.1), at 6 p.m.—Mr. H. A. V. Bulleid: "Cinematography in Engineering".

Society of Public Analysts and other Analytical Chemists, Biological Methods Group (at Gas Industry House, 1 Grosvenor Place, London, S.W.1), at 6.15 p.m.—Annual General Meeting: at 6.30 p.m.—Scientific Papers.

Society of Instrument Technology, Midland Section (at the Arden Hotel, New Street, Birmingham), at 7 p.m.—Mr. E. Simpson: "Optical Devices—Simple Optical Devices Applied to Weighing and Measuring".

Friday, December 17—Saturday, December 18

Association of Universities of the British Commonwealth (at the University of London, Senate House, London, W.C.1).—Conference of the Universities of Great Britain and Northern Ireland.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Research Assistant in Biochemistry, and a Technical Assistant in Biochemistry—The Secretary, Department of Pharmacology, Medical School, The University, Birmingham 15 (December 18).

Unestablished posts at the National Physical Laboratory, Teddington, in connexion with work which is being undertaken to promote the use of automatic control devices in industry—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.384/48A (December 18).

Senior Laboratory Technician with special experience in biochemistry—The Group Pathologist, Archway Hospital, London, N.19 (December 18).

Mathematicians (Senior Scientific Officer grade) at a Ministry of Supply research and development establishment near London for (*a*) theoretical investigation into the detonation of explosives, (*b*) numerical analysis of problems in applied mathematics, and (*c*) work on fluid mechanics—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.391/48A (December 18).

Mathematicians and Mathematical Physicists (Scientific Officer grade) for work in solid and fluid mechanics and high-speed gas dynamics, statistical mechanics and quantum theory, statistics, in Ministry of Supply research and development establishments in and near London—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.392/48A (December 20).

Lecturer in Industrial and General Psychology in the University of Western Australia—The Agent-General for Western Australia, 115–116 Strand, London, W.C.2 (December 20).

Lecturer in the Department of Biochemistry—The Registrar, The University, Liverpool (December 24).

Research Assistant in the Department of Chemistry—The Registrar, The University, Manchester 13 (December 24).

Assistant Experimental Officers to assist with performance testing of aircraft at a Ministry of Supply establishment in Wilts—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.393/48A (December 30).

Professor of Physics, and a Lecturer in Bacteriology, in the University of Queensland—The Secretary, Association of Universities of the British Commonwealth, 32 Woburn Square, London, W.C.1 (December 31).

Lecturer in Applied Psychology in the Joint Department of Psychological Medicine of King's College and the Royal Victoria Infirmary—The Registrar, King's College, Newcastle-upon-Tyne (December 31).

Lecturer (Grade III) in Chemistry—The Registrar, Queen Mary College, Mile End Road, London, E.1 (December 31).

Physicist (either Lecturer or Assistant Lecturer grade) in the Department of Textile Industries—The Principal, Municipal College of Technology, Manchester (January 3).

Reader or Senior Lecturer in Biochemistry in the University College of the West Indies—The Secretary, Special Committee of the Senate on Higher Education in the Colonies, University of London, Senate House, London, W.C.1 (January 15).

Civil Engineers (Hydro-electric Design Section), a Mechanical Engineer (Hydro-electric Design Section), and Mechanical Engineers (Mechanical Section), in the New Zealand Government Department of Works—The Official Secretary, Office of the High Commissioner for New Zealand, 415 Strand, London, W.C.2 (January 15).

Senior Lecturer or Lecturer in Anatomy—The Registrar, The University, Sheffield (January 22).

Chair of Applied Chemistry, the Chair of Applied Physics, and the Chair of Applied Mathematics, in the New South Wales Technical University—The Agent-General, New South Wales Government Offices, 56 Strand, London, W.C.2 (January 25).

Senior Lecturer or Lecturer in Mathematics, and a Senior Lecturer or Lecturer in Physical Chemistry, in the University College of the West Indies—The Secretary, Inter-University Council for Higher Education in the Colonies, 8 Park Street, London, W.1 (February 15).

Chair of Anthropology in Auckland University College (University of New Zealand)—The Secretary, Association of Universities of the British Commonwealth, 32 Woburn Square, London, W.C.1 (March 1).

Lecturer or Assistant Lecturer in Anatomy in the University College of the West Indies—The Secretary, Senate Committee on Higher Education in the Colonies, University of London, Senate House, London, W.C.1 (March 1).

Botanist (male) to undertake cytogenetical research on sugar cane at the British West Indies Central Sugar Cane Breeding Station—The Under-Secretary of State, Colonial Office, Research Department, Sanctuary Buildings, Great Smith Street, London, S.W.1.

Assistant Sugar Technologist in the Imperial College of Tropical Agriculture, Trinidad—The Secretary, Imperial College of Tropical Agriculture, Grand Buildings, Trafalgar Square, London, W.C.2.

Demonstrator (woman) in the Department of Anatomy—The Secretary, Charing Cross Hospital Medical School, 62 Chandos Place, London, W.C.2.

Organic Chemists (2) to undertake research initially on the chemistry of vulcanization, a Physical Chemist to study problems arising in the oxidation of rubber, a Colloid or Physical Chemist for fundamental studies in surface chemistry, a Colloid or Physical Chemist for applied research on rubber latex, a Rubber Technologist, and a Latex Technologist—The Director of Research, British Rubber Producers' Research Association, 48–52 Tewin Road, Welwyn Garden City, Herts.

Candidate (with a university degree in chemistry) to organise collation and indexing of chemical abstracts and to supply information to the chemistry division of the Atomic Energy Research Establishment, Didcot—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.1021/48A.

Biological Assistant (with degree in physiology or zoology)—Mrs. Simpson, Courtauld Institute of Biochemistry, Middlesex Hospital, London, W.1.

Physicist (preferably with some research experience) to study rheological properties of yarns and filaments—The Secretary, British Rayon Research Association, Bridgewater House, 58 Whitworth Street, Manchester 1.

EDUCATIONAL ADMINISTRATION

TWO recent broadsheets by P.E.P. ("Councils and their Schools") have directed attention to the local administration of education and its implications for democracy. The first, which is mainly concerned with the administrative structure of education in Britain, is introduced by the two pertinent questions : "Can provisional standards of efficiency be achieved if real responsibility rests with the ordinary citizen ? If not, does the interest of the child demand that the management of its education be surrendered wholly to the expert specialist ?"

The 1944 Act provided for an administrative framework in which a harmony of democratic control and technical efficiency could be achieved, and in this broadsheet an account is given of the hierarchy of education authorities, of the composition and functions of local education committees and of schemes of divisional administration in county areas. The second broadsheet discusses educational administration on the level of the individual school, as well as parent–teacher associations and other voluntary organisations connected with the schools.

In examining the machinery of local educational administration, the writers of the first broadsheet have brought together, in a form not otherwise readily accessible, information about the size and populations of the local education authorities and divisional executive areas as well as methods of co-opting members on to education committees. As they rightly point out, assessment of the merits and defects of the 1944 Act can only be tentative, because several of its main provisions have not yet been implemented and many bodies have only recently been constituted.

Some general principles of educational administration have been clearly defined by the Act. The relation between the central Ministry of Education and the local education authorities has been significantly altered. Instead of being merely advisory, the Ministry of Education is now more an executive agency possessing the right to make final decisions on many of the administrative schemes and policies of the local education authorities. This change in the Ministry's function has been unusually prominent during three years of acute shortage of man-power and materials necessitating direct control of available materials from the centre, and many local education authorities are finding it increasingly difficult to distinguish the new permanent statutory functions of the central department from its recently acquired temporary functions. Although these are due to the pressure of special circumstances, local education authorities are feeling the limitation of their sovereignty more acutely than they might otherwise have done, and tend to forget that there is considerable scope for local initiative. The most important elements of educational policy, for example, are the conduct and curricula of schools, and these are still subject to local decisions. Moreover, no significant intermediate regional agencies have been developed, and contact with the Ministry is still direct. His

Majesty's inspectors possess no executive functions except that they may approve certain items of expenditure.

Under the 1944 Act, the Ministry and the local education authorities are thus clearly defined as the chief levels of administration. The Act also provides for a considerable degree of decentralization. In county areas divisional executives have been established, while in all areas managers and governors have to be appointed for individual schools or for groups of schools. This, at least, is the theoretical division between the different levels of administration. In practice the division is less clearly defined, and the place of the divisional executive has proved to be one of the less happy developments of the 1944 Act. Divisional executives were created as a compromise between those who believed that education administration should be vested solely in the county and county boroughs, and those who thought the larger non-county boroughs and urban districts should become local education authorities in their own right. Neither faction has been satisfied. Schemes of divisional administration exist in only thirty-eight counties, and in twenty-one of these there are only one or two divisional executives. Most of the divisional executives set up under county schemes are *ad hoc* bodies and often do not sufficiently represent a community of interests to interpret local views effectively. Yet, the broadsheet concludes, "in spite of all the problems and inconsistencies found within the system, it appears that the chief purpose of the divisional schemes—the participation of a larger number of people, and the expression of local interests, in educational administration—is being achieved. The new method is costly and generally rather slow, for the delegation of functions involves the use of more officers, together with delays in passing on reports and in waiting for decisions from one committee to another on the different tiers of administration.".

While this cautious optimism might be justified in some cases, many divisional education officers are feeling acutely frustrated and, as their president, Alderman C. Barton, M.P., said to the recent annual conference: "While there is this apparent tendency towards a broader interpretation of the powers of divisional executives, it is true to say that the restrictive effect of over-elaborate regulations, highly centralized control of supplies, and quite minor details of administration all tend to weaken the real effectiveness of delegated powers. In many cases, too, the stringency of financial control exercised by the county council reduced the delegation to a mere farce."

Nor is discontent confined to the divisional education officers themselves. Before the introduction of divisional executives, some further education establishments in county boroughs were under the control of the county education authority. Now they come under the dual control of both the county authority and the divisional executives, and heads and principals of these establishments are placed in a dilemma as to the proper arbiter of their problems. In certain matters the head is instructed to refer to the divisional executive; in others to the county authorities; on occasion to both.

After three years experience of divisional executives there is a growing body of opinion that they have no executive place in educational administration and that they should be abolished in favour of a second tier of local administration. This should be made up of those people in intimate touch with the schools, the governors and managers. Selected governors and managers could form local educational advisory committees served by a staff whose duty it would be to keep in touch with schools, teachers, parents, managers and governors.

It is with the composition of governing and managing bodies of schools and the link between parents and teachers that the second broadsheet is chiefly concerned. Starting with the assumption that most people have some real interest in schools and should possess some method of making their influence felt, the broadsheet reviews the means whereby the various interests and experience of different kinds of people could be brought within the administrative system. Besides the establishment of divisional executives, the 1944 Act provides for co-option to education committees and, for every school maintained by a local education authority, a body of governors for secondary and managers for primary schools. These bodies have been only slowly established, and the problem of finding people to serve on them has frequently been the cause of delay. The 1944 Act provides for the grouping of schools, and, usually from expediency, this provision has been widely used. Like most expedient solutions the grouping has proved to be widely unpopular, particularly with those head teachers who are trying to build up local pride and interest in their schools.

Most appointing bodies are trying to discharge their responsibilities conscientiously; but they have been seriously criticized for doing too many jobs themselves instead of bringing new people into local administration. Their reply that new people cannot be found is more a commentary on the narrowness of the contacts of local representatives than of the shortage of public-spirited citizens. "Councillors do not always look beyond the members of their political party and their circle of friends."

The Ministry of Education has issued model articles of government which have been generally used by local education authorities in preparing their schemes for government and management. A division of responsibility is suggested in which "the L.E.A. would have the right to settle the general educational character of the school and its place in the local system. Subject to this general responsibility the governors would have general direction of the conduct and curriculum of the school. The headmaster or headmistress would control the internal organisation, management and discipline of the school, and would also have the power of suspending pupils, subject to a report being made forthwith to the governors and the L.E.A." This provides a *modus vivendi* between the local education authority and the governors and managers. Where there is no system of divisional administration these school bodies are the only local agents of the education authority. "Wherever there is a three-tier system of administration, competition and conflicts between the different levels are more likely to arise. On each step of the hierarchy there is a latent and sometimes active conflict between those which are immediately above and below each other. The local education authorities have very much the same attitude towards the Ministry of Education as the divisional executives have towards the local education authorities."

It is difficult for divisional executives to take an objective and positive attitude towards governors and managers, because they themselves are agents of decentralized and detailed administration. The boundary between their field of activity and that of the school boards is often blurred, some of the functions assigned to them belonging in principle to governors and managers as well.

It is also easy to forget that the object of educational administration is the individual school and the effect it has on the children in the schoolroom and the playground. The interpreters of educational ideals are the teachers in the schools, and their relationship with governors and managers is the most difficult and subtle problem of all. Primarily this is a relationship which has to be worked out amicably with head teachers; but "in a democratic system it is important that assistant teachers should feel that there is someone who, in matters of discipline and promotion as well as in the day-to-day routine of the school, is there to hold the balance and to see that justice is and appears to be done".

The authority of governors and managers must be wisely and tactfully used and rests on the fact that the head and his staff are the servants of the community; the authority of the school board is a sanction against abuse of power and neglect of duty.

At the school the most vitally concerned representatives of the community are parents. Yet they are the least organised, and their official place within the educational system is that of bystanders rather than of active participants. It is rare for them to sit on committees or act as governors or managers, because they are mothers and fathers and for no other reason. It is only through parent or parent–teacher associations that they can nominate representatives and make representations to governors or managers. Their more active participation in local education administration will depend on whether parent associations intend and are able to take part in the running of the nation's schools. The aims and associations of these parent or parent–teacher associations are very varied, and they seem to grow more freely in schools which serve a socially homogeneous area than in others; they exist most frequently in artisan and middle-class neighbourhoods and are found more often in nursery and secondary schools than in primary. Examples of the work of parent–teacher associations show that they can be a powerful instrument of educational progress. Their effectiveness can be considerably increased if the basis of association were communal rather than sectional; parent–teacher groups which take an active interest in all the broader aspects of education are the exception rather than the rule. There might be much more concern to form such groups if the reward of representation on education committees and similar bodies were offered to them. Examination of local administration suggests that too narrow a field is harvested in the choice of people to serve on education committees and local school bodies. The belief among councillors that the verdict of voters at a council election should be the only passport to participation in local government should give way to the conviction that education should have a wider appeal than that of ordinary local government and politics. Many parents would be glad to serve on government and managing bodies and local education committees if given the chance. Local education administrators should possess the will and the wit to bring them in. In so doing they would do well to remember the prudent rule of the London County Council, that no parent may become a manager while he has a child in the school concerned; parents with children who have left school may be the people to nominate.

TEN YEARS PROGRESS IN HORTICULTURAL SCIENCE

Hormones and Horticulture

The Use of Special Chemicals in the Control of Plant Growth. By George S. Avery, Jr., and Elizabeth Bindloss Johnson, with the collaboration of Prof. Ruth M. Addoms and Prof. Betty F. Thomson. (McGraw-Hill Publications in the Botanical Sciences.) Pp. xi+326. (New York and London: McGraw-Hill Book Co., Inc., 1947.) 27*s*.

TWELVE years ago Avery and Burkholder, with other collaborators, translated "Die Wuchstofftheorie" (Boysen-Jensen) and published a very useful introductory account of "Growth Hormones in Plants" which reviewed the literature concerned with the discovery and isolation of highly active substances from plant tissues, and with the application of these substances and chemically prepared compounds to plants. The ensuing interval has witnessed a rapid and wide extension of the list of synthetic compounds of very high activity, and has also afforded some, but perhaps not as yet sufficient, time in which to estimate the value of their practical application on a commercial scale to cultivated plants. The present volume deals with this expansion and the more practical applications, as the sub-title indicates.

The preface contains the remark that, "a chemical revolution is sweeping through the agricultural world"—others may think it is seeping through some parts of the world—and that, "by the application of minute amounts of growth controlling hormones we enter an important new era". Whether or not such bold claims be true, there can be no doubt that the diversity of the uses to which these substances can be put affords great interest to chemist, botanist, horticulturist and practical growers of many crops. To cater for such diverse readers the text has been prepared on broad general lines, without undue technicality.

The term 'hormone' is used in the widest possible sense, to permit, for example, the inclusion of a discussion of the use of dinitro-cresylic acid to thin out fruit blossoms, and the application of ethylene chlorohydrin to terminate dormancy (here reverting to the classical derivation of the term). Somewhat surprisingly, a chapter is included on the use of colchicine in the production of polyploid varieties.

A tabular presentation of the results of many experiments, made with a fairly wide range of chemical substances on many plants in an endeavour to facilitate plant propagation by acceleration of rooting from cuttings, is a valuable feature; it occupies a quarter of the whole text and is even then far from complete. A further list of unresponsive plants is provided; but the discussion of the results from the point of view of the later growth of the stimulated cuttings is perhaps not sufficiently critical. The statement that the use of such compounds is now standard practice does not generally apply to Great Britain.

The extensive tests made in America on the control of the pre-harvest fall of apples, by means of both sprays and aerosols, are well reviewed; as yet the difference in response shown by varieties remains to be fully explained; but in wind-swept districts this treatment has proved of high value, especially overseas. Another chapter is concerned with the stimulation of the ovary by chemical means and the subsequent seedless development of the fruits, a subject of current interest at research stations in Great Britain, where the process of parthenocarpy is being analysed into distinct phases. As this example shows, it is well-nigh impossible for any text to be quite up to date in such a subject. Again, a valuable table shows the range of plants that have responded to the applied chemicals. The authors have very rightly taken up a more critical attitude when reviewing the application of such compounds to seeds in attempts to stimulate early growth; these have been generally unsuccessful. As elsewhere in the book, there are helpful illustrations showing the injury that high concentrations may cause to plant tissues, and lists of the plants that have been damaged by selective weed-killers are given.

Prominent specialists have co-operated with the authors by supervising the preparation of the reviews of their own particular subjects, so that the text has an authoritative air; each chapter concludes with a general evaluation of the methods reviewed, although there is a slight tendency towards a favourable verdict discernible in the judgments. The chapters are briefly summarized, and selected references are freely provided. Author and subject indexes are also provided. The format maintains the well-known high standard of presentation associated with the publishers.

In such a rapidly developing subject, plant physiologists, after reading this book, are left to work out their own theories, and to discard their older ones; chemists will make new substances of yet greater activity, and no doubt together these workers will evolve new theories to explain the relationship between chemical structure and physiological activity. The horticulturist must try repeated tests with more varieties of his plants; no one can yet predict the reaction of related species in regard to weed-killers. But all these workers, together with a body of present-day and future students, will be grateful for this review of a decade's progress in applied science.

M. A. H. TINCKER

GOODNESS DEFINED

The Definition of Good

By Dr. A. C. Ewing. Pp. vii+215. (London: Routledge and Kegan Paul, Ltd.; New York: The Macmillan Company, 1947.) 12*s*. 6*d*. net.

FROM age to age, men have contemplated the problem of good; not infrequently, however, they have found themselves discussing what *things* are good, an entirely different question. Dr. A. C. Ewing is quite clear; his concern is with the former. This being so, he sets out to offer stout resistance to subjectivism and to naturalism in ethics. Why exactly does he do this? Because these tenets erode, as it were, any rational basis, and therefore render the superstructure of moral obligation insecure. The approach is positive and impressive—criticism, counter-criticism and the development of an appropriate alternative. The author modestly (and no doubt rightly) declines to put pressure upon "people to do what they know to be their duty"; unluckily, however, the number of readers of this book cannot be expected to be very great, and outside them must be a multitude by whom guidance—perhaps even direction—would willingly be accepted. In a word, we need an interpreter, somebody like Thoré, who in his day demonstrated to the uninitiated the power and majesty of the Barbizon painters; for, power and majesty these pages possess, but they are not easy reading.

An example occurs quite early (p. 4) in dealing with the advance of scepticism in ethics. The author fastens upon the belief that, in the minds of many, ethics are bound up with religion. This may well be so; but few would deliberately maintain that these activities are identical, or that the failure to hold to the one necessarily—or even probably—invalidates the other. As Dr. Anderson Scott once put it, they "interlock", a phrase which at once suggests that they can well be separated. And separable they must be, if both are to fructify.

Again, the axiological dilemma—a matter of taste rather than of objective truth—admits of no answer beyond that expressed with exceptional beauty and humility by the late Prof. A. E. Taylor (1926), that we shall never find what we are not sincerely looking for, and very likely value almost at zero. The instrument is there, but the will to use it is not.

Ethics thus emerges as a study *sui generis*, incapable of reduction or derivation to or from any other subject. In an illuminating chapter, concepts like good, right, obligation, are said to be capable of being related to some non-ethical forms, without the possibility of identity with any combination of such. Nevertheless, on the next page, the proof of the pudding ['s goodness] is [still] in the eating, implication and all.

'Good' is then subjected to analysis in terms of 'ought', using Moore's expression "worth having for its own sake", and the pro attitudes of Ross. 'Fittingness' becomes the king-pin of ethics rather than moral obligation. The author gives three excellent reasons for this choice, the strongest—it seems to me—being that belief that the proposed act is fitting is a necessary (and sufficient ?) state of mind to be in before any moral obligation can be willingly accepted. Inversion is easily seen to make nonsense.

One cannot expect to discuss a book on ethics without trespassing over other cultivated ground. The very nature of the subject invites excursions;

there is no trespass without wilful damage, and a little *Ausflug* can be wholly innocuous. Such a venture is rendered attractive by what Dr. Ewing has to say about art, or rather about works of art. 'Right' and 'harmonious' are words applicable to composition and balance; it is possible perhaps to go further and to assert that any "*merely* [my italics] rational analysis" is wholly incapable of adequate discernment in matters of æsthetic fittingness. The interesting thing is, however, that this is precisely the upshot, in analytic form, of Ruskin's lovely passage in his "Law of Help" ("Modern Painters", vol. 5), wherein he stakes his all upon composition as an individual achievement. Without it there is no picture; it is the creation of *that* artist, and of nobody else.

All these meditations may serve to show how rich in content is "The Definition of Good", and more, how valuable in suggestiveness. The historical pattern of ethical thought is present throughout as an unobtrusive background against which the author hangs his own definition, set off in a delicate frame. Yet he will not expect a crowd to be there gazing at it; in a better world there might be,

> "But knowledge to their eyes her ample page
> Rich with the spoils of time did ne'er unroll. . . ."

F. I. G. RAWLINS

OPERATIONAL CALCULUS AND ITS APPLICATIONS

Modern Operational Calculus

With Applications in Technical Mathematics. By Dr. N. W. McLachlan. Pp. xiv+218. (London: Macmillan and Co., Ltd., 1948.) 21*s*. net.

THIS book is intended as an introduction to operational calculus based upon the transform of $f(x)$ defined by

$$\varphi(p) = p\int_0^\infty \exp(-pt)f(t)dt,$$

that is to say, the Laplace transform multiplied by p. The function $\varphi(p)$ so defined is identical with what Heaviside called the operational form. The advantage of the present treatment over Heaviside's is that the theorems of operation can be placed upon an impeccable basis without the necessity for acts of faith. The contents are: 1, the Laplace transform; 2, rules of the operational calculus; 3, solution of ordinary linear differential equations with constant coefficients; 4, solution of partial linear differential equations with constant coefficients; 5, evaluation of integrals; 6, derivation of Laplace transforms; 7, Laplace transform for a finite interval; impulses.

This last chapter is stimulating and makes accessible the theory of a method of outstanding importance. There are six appendixes concerning matters on which the reader should be more fully informed. These articles form what the author calls the "mathematical limit gauge". Indeed, a valuable feature of this work is the actual checking of the validity of operations, such as inverting the order of integrations, integration of infinite series, term-by-term differentiation and so on.

Although the book is intended for postgraduate engineers and technologists, it will be seen from the foregoing remarks that the presentation is more rigorous than is usual in this kind of work. This departure is greatly to be welcomed, for should a costly design be based upon intuitive reasoning and the reasoning prove false, the result may be disastrous.

This book will no doubt appeal to a wider class of readers than the author expects. It should certainly be regarded as indispensable by all engaged in the many branches of science in which the operational calculus, to which Dr. McLachlan has made important original contributions, is a powerful tool.

L. M. MILNE-THOMSON

AN INTRODUCTION TO RADIO ENGINEERING

Essentials of Radio

By Morris Slurzberg and William Osterheld. Pp. xii + 806. (New York and London: McGraw-Hill Book Co., Inc., 1948.) 36*s*.

THE object of this book, according to the preface, is to describe at an intermediate level the principles of operation of thermionic valves and their associated circuits. It is intended for students at technical institutes or for radio technicians wishing to improve their basic knowledge of the operation of radio and electronic equipment; and, while it deals primarily with the applications of valves and associated circuits to radio receivers and transmitters, it serves also to give a general background to other industrial applications of electronic techniques.

The book achieves its declared purpose very well. For this very reason, the serious engineering student proceeding to a university degree is not likely, however, to find it very useful. It is essentially a technician's rather than an engineer's text-book.

The reader is assumed to have an elementary knowledge of electricity and magnetism, the authors having wisely avoided the fault, all too common in books of this sort, of beginning their book with an elementary course on electricity and magnetism. The reader's knowledge is 'refreshed' at appropriate points by restating fundamental relations in elementary theory in an appropriate practical form. Though the purist will find something to complain of in many of these practical restatements, the class of reader for whom the book is primarily intended is not likely to suffer much on account of an occasional lack of rigour. The analogy between radio and coal supply in Chapter 1 seems rather unnatural, and is unlikely to add to the understanding of the subject.

In spite of the title, the book deals almost exclusively with equipment. Wave propagation, though briefly mentioned, is not dealt with adequately. The appendixes provide much useful reference data in a convenient form, although, of course, the symbols and terminology are American, as also is the bibliography. From the point of view of the British reader, at least, the latter point is rather a pity since, though the field is necessarily not so large as the American, there are a number of British publications which could usefully have been included.

The book is excellently produced, as we have come to expect of books from these publishers, and the radio technician and others concerned with the operation and maintenance of electronic equipment will find it a useful general text- and reference-book.

W. R.

A Hundred Years of Chemistry

By Prof. Alexander Findlay. (100 Years Series.) Second edition. Pp. 318. (London: Gerald Duckworth and Co., Ltd., 1948.) 21*s.* net.

THE numerous admirers of Prof. Alexander Findlay's writings will welcome this new and revised edition of a remarkably interesting and useful book. His masterly review of a century of effort and achievement in the constantly widening domain of chemistry constitutes a great tribute to the author's power of taking a comprehensive view of a subject of bewildering complexity and expressing it in a way as attractive as informative. The book offers something to all who have an interest in chemistry; its character is such that it will be equally at home on the chemist's favourite bookshelf or in the lending or reference section of a library.

The new edition takes cognizance of the outstanding advances that chemistry has made in the last ten years, notably in the fields of atomic constitution, artificial transmutation of elements, nutrition, and medicinal specifics. During this fateful period, as the author remarks, "we have been the witnesses of one of the greatest achievements of the human mind, the utilization of atomic or nuclear energy. That this great achievement should have found its first use in human and material destruction by an atom-bomb is one of those tragedies which are a constant challenge to man's moral nature but which do not diminish the greatness of the achievement or make more difficult the application of man's knowledge to beneficent ends." In this work Prof. Findlay maintains his high reputation for accuracy; the only error of any note that has caught the eye of one with a peculiar interest in the immediate subject is the usurpation of hydrogen by hydroxyl in the molecule of chloroiodomethanesulphonic acid (p. 65).

The numerous footnotes illuminate in a striking way the writer's painstaking care and industry in going to original sources for his detailed information. The thumb-nail sketches of celebrated chemists given at the end of the book under the heading of "biographical notes" are very apt and replete with the concise facts so often needed and so hard to find.

JOHN READ

Historical Geology

The Geologic History of North America. By Prof. Russell C. Hussey. Second edition. Pp. xi+465. (New York and London: McGraw-Hill Book Co., Inc., 1947.) 19*s.*

THIS account of the geological history of North America is intended for students and readers interested in the cultural aspect of the science. The author, like all geologists, believes that a knowledge of the major events in the history of the earth should be part of a liberal education. Since a new edition has been called for only three years after the first publication of the book, it appears that he has attracted the public he desires and deserves. This revised edition has been simplified by removal of some material (an all too rare operation in the preparation of new editions) and has been brought up to date, and better illustrations have been given where possible.

The arrangement follows that of the first edition. First are presented the general principles of historical geology, the organisation of the geological record, the nature and significance of fossils and the main concepts of evolution. Special aspects of these general principles are developed in the account of the geological history of North America which follows. For example, the causes of marine transgressions are discussed with the Cambrian, the habitats of marine animals with the Ordovician, coral reefs with the Silurian and so on. For each geological period, the lands and seas and their sediments, the climate, crustal disturbances and life are dealt with in this order so that the story keeps moving. Emphasis throughout is placed on the development of life in this story, and this emphasis is increased as we approach modern times. The account of Tertiary life includes the geological history of the horses, elephants and other mammals, and the last chapter, one of more than thirty pages, deals with that of man. The illustrations, many from the great American museums, are abundant and mainly excellent. In spite of its sub-title, this book will be of service outside the United States as well as within, for it presents the broad essential principles by which the history of the earth's crust everywhere should be read.

The Mineral Key

By Howard B. Graves, Jr. Pp. viii+178. (New York and London: McGraw-Hill Book Co., Inc., 1947.) 20*s.*

MOST of this small book consists of mineral identification tables which are preceded by introductory chapters on equipment and chemicals needed and methods of identification. The determinative tables list some six hundred minerals, classified primarily according to colour, streak, cleavage and presence or absence of water, but optical properties and specific gravity are not included. Isomorphous series are each shown under one species, and varieties are omitted: amethyst and agate are, for example, excluded although many rare minerals are listed. The tables will be useful to experienced mineralogists, more particularly for determining opaque minerals; but in a book intended for amateurs more emphasis should, perhaps, have been placed on the caution necessary in identifying minerals with certainty. The price seems rather high for a book of this format. P. A. S.

Insect Pests of Glasshouse Crops

By Prof. Herbert W. Miles and Mary Miles. Second edition, revised. Pp. 200+24 plates. (London: Crosby Lockwood and Son, Ltd., 1948.) 15*s.* net.

A SURPRISINGLY large number of species of insects and related small animals occur in glasshouses and cause injury to the plants that are grown therein. A perusal of the present handbook will convince the reader on this point: at the same time it will enable him (or her) to recognize any of these creatures that he is likely to come across. The grower, whether he has only a conservatory or farms an acre or more of glasshouses, will find just the sort of information that he needs and what control measures are best suited for any particular enemy of his plants. The first edition of the book appeared in 1935, and the present issue is a revised version with some modification as regards the presentation of the text and the addition of several new illustrations. Since the book no longer has pages of trade advertisements incorporated, the increase of price from 8*s.* 6*d.* to 15*s.* is reasonable under present-day conditions. Well printed and illustrated, and with a good index, it is indeed excellent value for the price.

A KINETIC APPROACH TO THE THEORY OF THE STRENGTH OF GLASS

By S. M. COX
Wear Glass Works, Sunderland

THE theory advanced by A. A. Griffith[1] in 1920 has served as a background to subsequent theories of rupture in brittle materials. The solid is regarded as an elastic continuum containing microscopic flaws, and the failure of the material under a stress less than that corresponding to the 'theoretical strength' (that is, as estimated from the heat of vaporization, or from Van der Waals' equation) is attributed to the enhancement of the stress in the locality of the flaws rather than to any intrinsic weakness of the material itself. Subsequent theories[2,3] have assumed the acuteness of the flaws to be modified either by chemical attack by the atmosphere or by viscous yield in order to account for the apparent decrease in strength of glass with increasing duration of load. This is but one of the difficulties which can only be met by rather artificial additions to the theory.

The advance in recent years of the theory of liquids suggests that a kinetic approach might directly resolve many of the difficulties—at least in so far as glass is concerned. Broadly surveying the phenomena connected with the fracture of glass, one is impressed by the consistency of some aspects and by the consistently variable nature of others. The glazier's control of the crack-direction, the geometrical simplicity of some crack-systems—the simple conchoidal crack and the familiar helixical cracks in tubing—these aspects are suggestive of elastic-continuum crack-propagation initiated by a flaw. On the other hand, there is the spread of results under tensile test, the dependence of strength on time, on sample size and on temperature; if these effects arise from intrinsic properties of the glass and are not due to the experimental conditions, an element of time, an element of size and an element of energy are to be accounted for. An atomic view provides three such intrinsic elements: there is the period and the energy of vibration, and the size of the atoms or ions themselves, and it is conceivable that the observed phenomena might be some macroscopic manifestation of the discrete nature of glass.

Kinetic treatment has been neglected on the grounds that the activation energy necessary for the spontaneous formation of flaws is too high, in comparison with the thermal energy, for the possibility of such an origin of flaws to be a significant factor except near the boiling point. This would certainly seem to be the case if one accepts Griffith's estimate that at least 10^8 atoms must synchronize and be in phase to initiate rupture. A little consideration will show, however, that this possibility cannot be dismissed so lightly. In the first place, a local discontinuity of any kind must cause a stress enhancement of the same type as that caused by a crack, and a local change in state of the material must provide such a discontinuity. There is now ample evidence to support the contention that atomic configuration-changes, characterized by comparatively small activation energies, can take place in glass. The large differences in volume associated with these changes become apparent in the annealing range. The necessary activation energy may then correspond to the annealing point rather than to the boiling point. Further, in the case of such 'configuration-flaws', the critical size, which must be achieved if the flaw is to grow, will be set by the relative stabilities of the two types of configuration and not by Griffith's criterion—which latter defines only the subsequent stage in the rupture sequence where the configuration-flaw gives place to the first true rupture. Finally, an immense number of opportunities are provided for the occurrence of a local accumulation of energy. The energy is so rapidly interchanged (vibration frequency 10^{12} cycles per second) and the atoms so numerous (Avogadro's number 10^{23}) that in a test lasting one second on 1 c.c. of glass the rare event is sought some 10^{35} times.

The problem of expressing the tensile strength in kinetic concepts must turn on the question of determining the conditions under which a local disorder will become cumulative. On Maxwell–Boltzmann theory all energies are possible, so there is no difficulty in supposing a single atom to become sufficiently energetic to leave its site in the array. The atom can only retain this energy for a time comparable with the period of its oscillation, unless its immediate neighbours are equally energetic. This event would also provide the opportunity for configuration-change, so that both the energy and the opportunity for a configuration-change would occur where a group of (say w) neighbouring atoms becomes activated. The experiments on annealing-range configuration-changes disclose that they are pressure-sensitive and reversible. If then the event in which the w atoms become activated occurs under stress, because this occurrence causes a stress enhancement at the boundaries of their locality, there will be a critical value for w, for larger values of which the extent of the configuration-flaw will grow and lead to eventual rupture, while for smaller values the flaw will have but a transient existence.

Taking into account the reversible nature of the change, an expression can be derived for the probability of such an event in terms of the temperature and stress. Assuming that each such event will lead to rupture, the tensile strength is given by setting this probability equal to one half—in accordance with the usual definition of the breaking point as that stress at which the chances of rupture and survival are equal.

$$\frac{\nu N t}{\tau}\left[A\left(\exp.\frac{S}{kT}-C\right)\exp-\frac{B}{kT}\right]^{w}=\frac{1}{2}.$$

In this expression νN is the number of different ways in which the w neighbouring atoms constituting a flaw-nucleus may be chosen out of the N atoms in the sample under a stress proportional to S; t is the duration of test, and τ the vibrational period of the atoms. A and C are constants depending upon the composition and temperature of the glass, and B is the activation energy for the configurational-change involved. It will be noticed that there is a minimum tension corresponding to $S = kT \log_e C$ below which the glass should not break, however large the sample or prolonged the test.

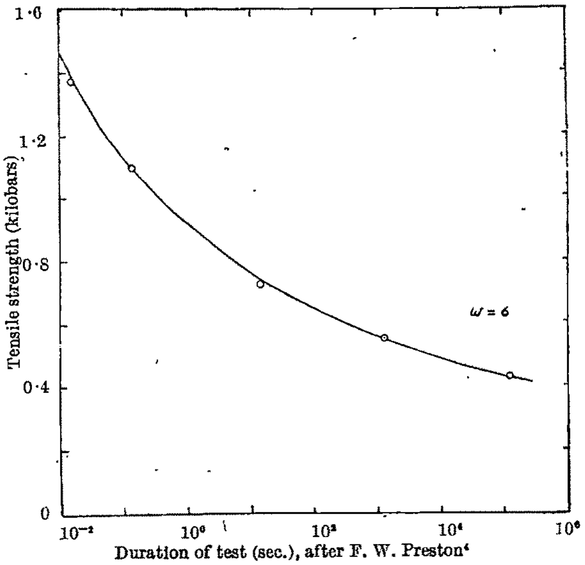

Fig. 1

The relations between strength, duration of test and sample size given by this expression are in good agreement with experiments, as may be seen in Figs. 1 and 2. The spread of experimental results is also predictable (Fig. 3). In all these figures the full line represents the calculated results and the crosses or circles the observed values. The derivation of the formula is given in more detail in work already published[9].

In making these comparisons the value of w must in most cases be found by trial. It is natural to suppose that the value of w for a surface flaw would only be half that for an internal flaw, for on purely geometrical grounds a flaw of half the volume of an internal flaw would be equally weakening on the surface—in the same way the roughness of the surface on an ionic scale will influence the strength because of the smaller value of w required to make an equally effective flaw. One has then the same type of explanation of surface effects as in Griffith's theory, but on a sub-microscopic level. One of the troubles with Griffith's findings was that his flaws should be visible, and at least in the ordinary course of events there is no visible evidence for them. On the contrary, as Murgatroyd has shown, visible single scratches are sometimes ineffectual in weakening the glass. This is an interesting point, because on the basis of the above equation, such a scratch—in spite of the enhanced stress at its edge—is not necessarily the most probable origin for the breakage; the size of the sample (N) must also be taken into account, and where the size is reduced to the area of the scratch, the probability of breakage from this particular locality is reduced in the ratio of this area to the effective area of the whole sample.

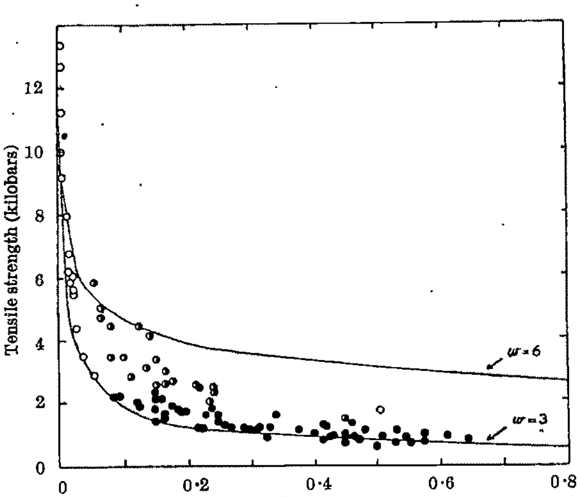

Fig. 2. o—o—, Data by A. A. Griffith[5]; ●—●—, data by E. J. Gooding[6]; ◐—◐—, acid-polished specimens

Another feature of brittle rupture which finds a ready explanation on this theory is the behaviour of the crack-propagation velocity and the nature of the broken surface. The velocity of crack-propagation is set by the calculable probability of the atoms at the crack-tip becoming activated. It has a maximum corresponding to the requirement that the energy cannot be transferred from atom to atom in a time less than τ. When this maximum is reached, there is no corresponding limit in elastic theory to the stress-enhancement due to the flaw; and a stage is reached at which the probability of breakage is not limited only to the crack-apex; but cracks also develop at an angle to the principal stress. This is the point at which the mirror surface gives place to the hackled surface so often observed on broken surfaces.

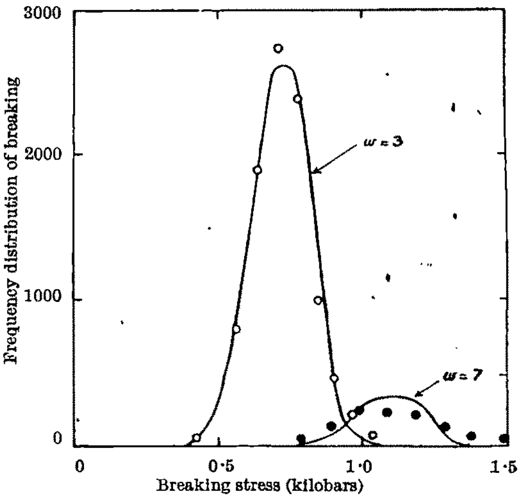

Fig. 3. o—o—, 9983 samples, after B. P. Dudding[7]; ●—●—, 115 fire-polished samples, after Holland and Turner[8]

The numerical assessment of the probabilities and the determination of the effect of temperature on the strength of glass is made difficult because one cannot assume that all atoms have average activation energies. A consequence of the random arrangement of the atoms must be a spread of activation energies, and as those of lower value are obviously of most significance, it would be necessary to have some knowledge of the shape of the distribution curve. Assuming the distribution of activation energies to be similar to the distribution of inter-ionic distances from X-ray data, a crude estimate can be made, and in this way it is found that the product of the quantities on the left-hand side of the equation given may well be of the right order, that is to say, one half.

To summarize, if the strength of glass does depend on the spontaneous development of flaws under the applied stress in the way described, then breakage can only occur if the stress exceeds a certain minimum. Above this minimum stress the probability of breakage increases with sample size and with time for the same reason, namely, that such increases provide increased opportunity for the rare event which is automatically recorded by the fracture of the specimen.

MINIMUM OXYGEN LAYER IN THE OCEAN

By Dr. R. B. SEYMOUR SEWELL, C.I.E., F.R.S.
University of Cambridge
AND
Prof. LOUIS FAGE
Institut Océanographique, Paris

THE fact that there is in every ocean a zone of minimum oxygen is of interest not only to the physicist and chemist but also to the biologist, and it is very desirable that we should know what influence this layer has on both the quantitative and qualitative distribution of the fauna, or, alternatively, whether this layer is to be attributed to the biological activity of the fauna and especially of the plankton. The facts that we possess regarding this problem are very impressive and are somewhat contradictory.

The depth at which this minimum oxygen layer is found differs in different oceans and in different regions of the same ocean. In the Atlantic its depth below the surface varies from 350 to 900 m. In the Indian Ocean, according to the results obtained by the *Dana* and the *Mabahiss*, the distribution of oxygen is less simple; the oxygen content of the tropical surface water decreases abruptly within the thermocline to an intermediate minimum, which at all stations north of the equator is found at a depth of about 150 m.; below this level the oxygen content of the water increases slightly and then again falls abruptly in those regions in which the Indian Intermediate Current flows southward at a depth of approximately 250–1,500 m., and at this depth the actual content may be well below 0·1 ml. per litre. In the Pacific the depth of this layer varies between 400 and 1,000 m.

Le Danois[1] considers that this zone of minimum oxygen is the result of stagnation of the water at this depth and the presence of what he terms 'fossilized' water. Wüst[2] concludes that in the Atlantic Ocean between lat. 45° S. and 20° N. the layer of minimum oxygen coincides with the boundary between the surface stratum and the Antarctic Intermediate Water, while farther north it marks the boundary between the surface water and the water that has flowed out of the Mediterranean Sea; he, too, considers that the low oxygen content is the result of stagnation or of very slow horizontal movement. Wüst[3] also claims that over the greater part of the Atlantic Ocean the depth of the layer coincides with the 8° C. isotherm; but in the North Atlantic between lat. 30° and 45° N., owing to the influx of Mediterranean water, this isotherm lies about 600 m. below the minimum oxygen layer. Vallaux[4] points out that in the Atlantic between lat. 0° and 20° N. the fall in the oxygen content, which commences at 200 m., reaches a minimum at the 400–800 m. depth, and thus stands in close relationship to the complete disappearance of the phyto-plankton and to the relatively great abundance which the zoo-plankton manifests at this level.

T. G. Thompson[5] and others show that there is a marked correlation between the minimum concentration of oxygen and the maximum concentration of carbon dioxide, and they claim that the reduction of oxygen is due almost entirely to the oxidation of organic matter at this depth. Seiwell[6] stresses that the minimum oxygen concentration may primarily be due to either a proportionally greater oxygen consumption per unit of time or a slower renewal by horizontal currents; and he suggests that biological activity plays an important part in fixing the minimum oxygen concentration at mid-depths. This may be brought about by a maximum concentration of oxidizable organic matter at the depth of the minimum oxygen concentration, or, if the supply of oxygen by horizontal currents varies with depth, by vertical variations of biological activity, causing the ratio, oxygen utilized/oxygen supplied, to be continuously increased as the depth of the minimum oxygen concentration is approached both from above and below. He points out that the minimum oxygen concentration in the western North Atlantic tends to occur at the level of the density value $\sigma_t = 27{\cdot}232 \pm 0{\cdot}008$, which implies that the settling velocities of organic particles are perceptibly slowed at this level, resulting in an increase of oxygen consumption per unit time. He adds, "however, the results of oceanic biological investigations have not yet furnished evidence for the adoption of this hypothesis".

Redfield[7] claims that it has been found that in the North Atlantic the phosphate maximum and oxygen minimum may be derived chiefly from the oxidation of organic matter within a few hundred metres of the surface in the region about lat. 40° N., and further that in the equatorial region additional phosphate is added to and oxygen removed from the water by processes other than isentropic movement, namely, by the sinking of decomposing organisms from the surface of the tropical ocean to considerable depths. In the belt between lat. 20° S. and 25° N. it is difficult to explain the observations without assuming that active decomposition is occurring down to a depth of at least 600–800 m. Harvey[8] maintains that the reduced concentration in the oxygen-poor layer is due, in part, to consumption of oxygen during the oxidation of falling particles of organic matter, coupled with slow renewal through eddy-conductivity from the surface layer and from the deep water below; minimum values are found in the most stable part of the water column, where the density of the water is increasing most rapidly with depth, and, furthermore, the size of these particles decreases rather rapidly with time. Thus we are faced with the question, "Is this oxygen consumption caused by bacterial action on dead or decomposing organic particles?"

Redfield[7] has pointed out that the quantity of such falling organic debris is not great in the relatively barren areas of the Atlantic, and that its oxidation is likely to be nearly complete before it has fallen as deep as the layer where the least oxygen is found. The work of ZoBell and Anderson[9,10] has shown that the number of bacteria that could carry out this destruction of organic particles is high in the photic zone of the ocean in the top 20 m., but then decreases extremely rapidly until it is at a minimum at about 500-m. depth, increasing again rapidly at the bottom in the sediments. ZoBell[11] claims that "considering that most of the organic content of sea-water is highly refractory to bacterial oxidation, it appears that the concentration of organic matter is near the threshold of the requirements for bacteria, which probably accounts for the paucity of bacteria in the ocean". It would thus appear to be very doubtful whether the minimum oxygen layer can be attributed to the bacterial decomposition of dead organic matter, and one must therefore consider the possibility that the living plankton may be the cause.

It is frequently stated that the total amount of living plankton steadily and progressively decreases with depth, and Schott[12] has given figures that indicate this very clearly. Off the Californian coast, at five stations carried out in 1933 at a point 100 miles west of Cape Arguello in Central California by the steamship *Pioneer* of the United States Coast and Geodetic Survey, the total plankton showed a steady decline from the surface downwards, and the minimum oxygen layer, with a concentration of oxygen as low as 0·2 ml. per litre, lay at a depth of about 100 m., with an increase of oxygen to more than 2·0 ml. per litre at greater depths. Hauls with the Nansen closing-net over intervals of about 100 m. showed that the total amount of plankton appeared to decrease uniformly with depth, so that there was less plankton below the oxygen-minimum layer than in it. Dr. Revelle, who participated in these investigations, states that at the time he thought that the controlling factor for the plankton concentration was food-supply, that is to say, organic material settling from the photosynthetic zone near the surface and being eaten as it sank. Sverdrup, Johnson and Fleming[13] (p. 872) state that on the coasts of California the diminution of pelagic life with depth is not in agreement with that of oxygen, since between 150 and 800 m. oxygen is almost entirely absent, but one captures Copepods and other planktonic forms at these depths. Bogorov[14] reached the same conclusion regarding the distribution of the Copepoda in the White Sea and Barents Sea. But this steady decrease in the quantity of plankton with depth does not always hold good. In the Gulf of Panama, A. Agassiz[15], during the cruise of the *Albatross*, found between 366 and 732 m. depth an azoic zone which contrasted strongly with the richness of life observed above and below this depth, and it is between 400 and 500 m. that in this region one finds the zone of minimum oxygen (0·6 ml. per litre). In the same region the observations made on board the *Dana* by Joh. Schmidt[16] and P. Jespersen[17] show a remarkable quantitative difference in the plankton; they found, in contradistinction to the observations of others, that the plankton is incomparably richer at a depth of 1,000–1,500 m.w. (500–750 m. depth) than it is nearer the surface at 50–300 m.w. (25–150 m. depth); the volumes captured per hour for a net having a diameter at the mouth of 1·50 m. are, on the average, 527 c.c., as compared with 262 c.c., the observed minimum of 105 c.c. occurring at a depth of about 600 m.w. (300 m. depth).

A study of the hauls of Copepoda made at different depths by various expeditions in different regions seems to indicate that, as one passes from the surface to greater depths in the tropical region, there is at first a steady reduction in the number of both species and individuals until one reaches a depth of some 400–500 m.; the species inhabiting this upper zone are clearly warm-water, surface-living forms. At this point the curve changes its direction and the number of species and individuals begins to rise again; these latter species are cool-water, deep-dwelling forms. The greatest concentration of individuals of these deep-dwelling species occurs at some distance above that of the greatest concentration of species, and in most cases seems to fall near the level of the zone of minimum oxygen (Sewell[18]). In this connexion it is of interest to note the results obtained during recent under-water sound investigations that have been carried out by the United States Navy Electronics Laboratory, San Diego, California. These investigations have revealed the presence of a deep layer in the ocean that causes a scattering effect. This scattering layer lies at or near the surface at night; but before sunrise it commences to descend and during the day-time is found to lie at depths ranging from 150 to 450 fathoms (274 to 823 m.); in the evening, starting before sunset, it ascends again to the surface. This layer seems to be present throughout the tropical and temperate regions of the Pacific, but was absent or only sporadically present in the Antarctic during the period of almost permanent daylight. In some regions double or even treble layers were detected at different depths.

It has been suggested that these layers of scattering may be due to the presence, and to the daily vertical migration under the influence of light, of a concentration of zoo-plankton, and that the double or triple layers may indicate that different species, or different stages of development of the same species, may be implicated. The most common depth at which the scattering layer was found is about 350 fathoms (640 m.), and hauls with the closing-net gave evidence that at about this depth there seemed to be indications of a considerable increase in the numbers of Euphausians and *Sagitta*.

Sverdrup, Johnson and Fleming[13] (p. 730) remark that "a few scattered observations indicate that organisms are found even when the oxygen content is as low as 0·1 ml. per L.". During the *John Murray* Expedition several hauls were carried out at intermediate depths at certain stations in the Arabian Sea; in each case the net used was one having a diameter at the mouth of one metre. Here the minimum-oxygen layer lies at a depth of 600–1,000 m., and in the table below is given the actual numbers of four species of Copepods that were taken in this zone:

Station identity number	186	172	76	172	76
Depth in m.	0–250	0–400	0–600	0–850	0–1500
Eucalanus attenuatus	—	250	—	473	—
,, *elongatus*	191	302	2,061	567	351
Rhincalanus nasutus	167	744	803	1,249	—
Pleuromamma xiphias	—	222	—	247	—
Oxygen concentration in ml. per litre	0·536	1·02	0·323	0·455	1·09
Duration of haul	1 hr.	2 hr.	1 hr.	2 hr.	1 hr.

The main haul was taken at the maximum depth indicated. These observations clearly point to the presence of a flourishing population, belonging to several species, in this zone of minimum oxygen; and for the maintenance of this relatively rich fauna there must be an equally rich food-supply.

Another point of interest is to be found in the prevalence at these intermediate depths of species that possess a red or purple coloration; this is particularly striking in the Crustacea and in certain species of fish. Above this level, planktonic animals tend to be colourless, while below it many species of fish are brown or black. In the words of Sverdrup, Johnson and Fleming, "the further examination of the distribution of such organisms and their adaptation to the extreme condition represents one of the fascinating biological problems".

Another problem that requires investigation is whether this minimum-oxygen layer forms an obstacle to the admixture of surface-living forms with those of greater depths. In this connexion Dahl[19] has pointed out that a large number of species of Copepoda are to be found in the upper stratum, while below this lies a second, extending down from about 300 to 1,000 m., in which there are only a few Copepods that are common to the upper layer; and the few species that are common to both strata are mostly rare in one while being numerous in the other, in which they are really at home. It is interesting to note that Grace Pickford[20] in a study of *Vampyroteuthis infernalis*, captured by the *Dana*, shows that the vertical distribution of this Cephalopod appears to be limited in all the oceans by the zone of minimum oxygen. According to Torsten Gislen[21], the minimum-oxygen zone will equally play a part in the distribution of the benthonic species; basing his conclusion on the catches of Echinoderms made by the *Albatross* off Panama and the California coast, he believes that not only is there a remarkable paucity of the fauna at a depth of 500–600 m., but also he shows that the species above and below this level are entirely distinct.

It is thus abundantly clear that a detailed study of this zone and of the fauna that inhabits it, as well as a comparison of the faunas above and below it, present a number of problems that are of considerable interest, not only to the taxonomist but also to the physiologist and biochemist; and it seems worth while, now that oceanographic investigations are once again being contemplated or actually carried out, to direct the attention of investigators to this zone.

USE OF LIQUID FUELS

CONFERENCE AT BIRMINGHAM

IN scientific research, and in the application to industry of the results of research, the problems encountered are of increasing complexity. Scientific workers engaged in this work feel the necessity for consultation or collaboration with specialists in fields other than their own. Indeed, it has become a commonplace that most industrial research problems require teams of experts from many branches of science and engineering. The interdependence of the various branches of science and technology has long been recognized; but collaboration between the corresponding societies has been practised to a noticeable extent only in comparatively recent years. Joint conferences, such as that held at the University of Birmingham during September 21–23, are therefore welcome not only for their immediate value, but also as tokens of the growing integration of science.

The Birmingham Conference on "Modern Applications of Liquid Fuels" was organised by the Institute of Petroleum and the Institute of Fuel, in recognition, as Mr. J. A. Oriel, the president of the Conference, put it, of their joint responsibility for ensuring that all kinds of fuel available in Great Britain are used with maximum efficiency. The scope of the Conference was wide, and while the use of oil fuels for prime movers, as in petrol and Diesel engines, was in general excluded, the seven sessions, into which the Conference was divided, furnished opportunities for the exchange of information, experience and opinion about the design, operation and performance of burners and furnaces, agricultural driers, Diesel rail traction-engines, the use of oil in the gas industry, and the principles of combustion-chamber design for the gas turbine.

One evening was devoted to a lecture on the uses of liquid fuel in domestic heating, largely based on the work of the Liquid Fuel Installations Committee of the Institute of Petroleum. This Committee is preparing a report on the use of liquid fuels for domestic heating at the request of the Minister of Fuel and Power, similar to the Post-War Building Studies arranged by the Ministry of Works in reference to electricity, gas, and solid fuels. The oil fuels chiefly used, for both space- and water-heating, are liquefied butane and other gases, kerosine, and Diesel oil. The development of modern domestic appliances burning kerosine was described, and attention was directed to their high thermal efficiencies; such appliances have many advantages in rural areas.

The Conference was concerned in the main, however, with the industrial application of oil fuels for purposes for which coal and petroleum may be used alternatively, and the chief scientific interest of the Conference, therefore, was the opportunity which it provided for making a comparison of the two fuels. In Great Britain, coal always has the advantage of lower cost, and the opinion is widely held that but for this advantage, oil would always be used in preference to coal. Oil has a higher calorific value, and is certainly easier to handle and store than is coal; and it is cleaner in use—qualities which account, for example, for the replacement of coal by oil for use at sea. Petroleum, moreover, has a very small content of mineral matter; this becomes concentrated in residual fuels by distillation, and the use of distillate fuels is accordingly entirely free from the troubles due to ash-formation which are associated with the use of coal. The same is, however, not true of residual fuel oils; although ash-formation is much less than with coal, it may give rise to serious problems, as, for example, in the gas turbine, where ash-deposition is a major obstacle in the development of this prime mover to use heavy fuel oils. Fuel oils, of course, still have a great advantage over coal in this connexion; but it is important to realize that the use of oil is by no means entirely free from the problems which attend the use of coal. Thus both fuels contain sulphur, and the fuel oils available for use in Great Britain often have high sulphur contents (two per cent or more) which may cause deterioration of product quality in the steel and metal industries. In this respect, therefore, the advantage frequently lies with coal or the fuels derived from it, namely, producer-gas and coal tar.

The oil flame has a higher radiation efficiency than the gas flame—a property which has contributed to the improved results which have been obtained in the manufacture of steel in the open hearth furnace by conversion to oil firing. Several other factors are, however, also involved, and there was considerable divergence of opinion at the Conference as to the relative merits of oil and coal in this and similar applications. In some instances, conversion to oil firing has shown little advantage; but the bulk of the evidence supports the conclusion that it leads to greater steel production. It is, in fact, probable that the use of oil has made an important contribution to the record steel output in Britain now being obtained. It cannot, however, be immediately concluded that conversion from coal to oil firing is necessarily advantageous to the steel industry.

In the first place, consideration must be given to the cost of any technical advantage, and the differential price of coal and oil in any particular locality is clearly a most important factor. This is illustrated very clearly by the American experience which was recorded in one of the papers contributed to the Conference. The steel industry in the United States was originally based on coal; but oil firing was adopted, at a time when fuel oil was relatively very cheap, with a consequent increase in thermal efficiency and steel production. At present, however, the supply position and the changing price differential have started a reverse trend from oil to coal firing. The combined use of oil and coke-oven gas has given good results, and it is suggested that other combinations, including such fuels as coke breeze and powdered coal, might be used with advantage.

A second factor in the achievement of improved results with oil firing is the greater ease of control which attends the use of oil. Partly in consequence of this, the application of oil firing has usually been made with greater instrumentation and scientific control, and it seems likely that improved results could also be obtained with producer-gas if similar methods were employed. This consideration suggests that the comparison between oil firing and conventional practice with producer-gas has not always been fair to the latter. It is certainly also true that the comparison has sometimes been unfair to oil firing because of unsuitable furnace design. Thus it has been shown that the jet action due to the greater velocity of the oil flame may result in a serious air inleakage which could be avoided in a furnace designed specifically for the utilization of oil.

The use of fuel oil in glass furnaces also gives the advantages of greater ease of control and increased rate of glass melting, but the intense radiation from the oil flame results in increased wear on refractories; and although increased efficiency could be obtained by greater preheat of the combustion air, it is concluded that oil firing is not at present economic in comparison with an efficient producer-gas system. It is evident that the assessment of the relative values of coal and oil firing involves many technical and economic factors.

It is not possible, in this short article, to do justice to the vast amount of technical information which has been provided by the many papers contributed to the Conference. Readers interested, for example, in the application of the Diesel engine to rail traction, in modern developments in agricultural drying processes, or in any of the other modern applications of liquid fuels in the field already indicated, will be well advised to consult the Conference records; when published, these will constitute a valuable work of reference which will perhaps be the major achievement of the Conference.

F. H. Garner

OBITUARIES

Dr. S. E. Sheppard

Samuel Edward Sheppard died in Rochester, N.Y., on September 29, aged sixty-six. Dr. Sheppard was born in Catford, and was educated at St. Dunstan's College, Catford, and University College, London. There he obtained the degree of B.Sc. by research in 1903, his thesis dealing with the theory of the photographic process and involving a repetition and extension of the earlier work of Hurter and Driffield. This work was greatly extended in his research for the D.Sc. degree, which was granted in 1906 for a thesis which was published in 1907 jointly with that of C. E. K. Mees under the title of "Investigations on the Theory of the Photographic Process". Much of the work had been published in a series of papers in the *Photographic Journal*, the *Transactions of the Chemical Society*, and in the *Proceedings of the Royal Society*.

In 1906 Sheppard was awarded an 1851 Exhibition for two years and went to Marburg, where he worked with Karl Schaum, professor of photo-chemistry and the editor of the *Zeitschrift für Wissenschaftliche Photographie*. Sheppard's work was on the molecular structure of sensitizing dyes and particularly of pinacyanol, the red sensitizer discovered only a short time before by Homolka, of the Hoechst dye-works. The study of the structure and behaviour of dyes like pinacyanol continued to attract Sheppard's attention throughout his entire life. After a year in Germany, Sheppard went to Paris, where he worked with Victor Henri at the Sorbonne on colloid chemistry.

In 1913 Sheppard accepted an invitation to take charge of the sections of physical and colloid chemistry in the Kodak Research Laboratory, which had just been organised under the direction of C. E. K. Mees at Rochester, N.Y.

His early work there dealt principally with the physico-chemical properties of gelatin, and a number of papers were published dealing with the measurement of the viscosity of gelatin solutions, the measurement of the jelly strength and the elastic properties of gelatin jellies, the setting and melting points of gelatins, the drying and swelling of gelatin, and the structure of gelatin in solution, in the jelly, and in the dry state. These early papers deal primarily with the definition of the properties to be measured, with methods of measurement, and with instruments for making the measurements. As soon as the methods were so perfected that reproducibility was possible, it became evident that further progress in the realm of the physical and chemical properties was dependent on the nature of the sample. This work culminated in 1929 in a description of a procedure for making a standard gelatin by methods easily reproduced in the laboratories. A scientifically valuable by-product of this work was the manufacture and consequent availability of such a standard de-ashed gelatin to laboratories in general, biological as well as chemical.

After the First World War, Sheppard began to turn his attention to the structure and properties of silver halide emulsions, and his first work took the form of a study of the distribution of the sizes of the silver halide grains in an emulsion, the intention being to work out the relation between this distribution and the sensitometric properties of the material. Thus began a long series of studies that are not yet completed, though much progress has been made in the last thirty years. At the same time, working with Dr. Ludwik Silberstein and with Mr. A. P. H. Trivelli, Sheppard began to consider the action of light on the halides and the nature of sensitivity, and about 1923 a series of papers was published on the theory of photographic sensitivity and of exposure, which resulted in the presentation of the concentration speck hypothesis, according to which the sensitivity was related to discontinuities in the silver bromide lattice, presumably due to some foreign substance. At the same time, a very notable group of studies was going forward on the measurement of size frequency distribution, which led to the development of microscopic methods by which the grain-size frequency distribution could be measured for practical silver bromide emulsions.

The well-known sensitizing property of gelatin in the photographic process led to a systematic study of the difference between photographic gelatins in their sensitizing power and the nature of the substance in gelatin which conferred sensitivity. By a painstaking series of analyses, it was found that the sensitizer inherent in natural gelatin was concentrated in the liquors obtained by the acid treatment of the raw material after liming; and eventually it was found that the chemical properties of the sensitizer corresponded to those of allyl thiourea, and that therefore the gelatin sensitizer was essentially one which could produce silver sulphide specks in the silver bromide crystals.

This discovery is perhaps the major advance made in Sheppard's scientific career. All further study of the photographic properties of gelatin, of the nature of the sensitivity of silver halides and of the latent image have been conditioned by it. Its publication won for Sheppard instant recognition. He was awarded the Adelsköld Medal of the Swedish Photographic Society in 1929, the Progress Medal of the Royal Photographic Society in 1928, and the honorary fellowship of the Royal Photographic Society in 1926. In 1928 he delivered the Hurter and Driffield Memorial Lecture to the Royal Photographic Society, and in 1930 received the Nichols Medal of the American Chemical Society.

From that time, Sheppard's scientific work covered a prodigious range of knowledge. Besides the work on the latent image, he studied such matters as the photovoltaic effects, that is, the electrical response of silver halide to light, the colloidal structure of film-base materials and their physico-chemical and elastic properties, the nature of development, and particularly the nature of dye sensitizing, the adsorption of sensitizing dyes to silver halides, the structure of the layers which they formed, and their sensitizing effects.

Sheppard realized that the solution of the problem of dye sensitizing would involve not only the coupling of the dye to the silver halide lattice by absorption, but also an understanding of the nature of the absorption of light by the resonance structure of the dye. Thus he studied the absorption spectra of dyes in various solvents, in vapour phases, and when adsorbed to surfaces. This is the field which was chiefly engaging his attention when his health failed.

While never robust, Sheppard enjoyed good health until a few years ago, when he began to have trouble with his eyes, which culminated in the loss of one eye from glaucoma. At the same time, his heart was affected, and continued to fail until in January 1948 he found it necessary to resign from his position with the Kodak Company.

More than any other single worker, Sheppard has been responsible for our present knowledge of the theory of the photographic process. He explored every section of the chemistry of that process, and everywhere his studies brought light.

C. E. K. MEES

Prof. Kornél de Kőrösy

WE regret to announce that Dr. Kornél de Kőrösy, professor of biology in the University of Budapest, died on July 14. Son of the famous Hungarian statistician, Joseph de Kőrösy, he was born at Budapest in 1879. As a student of medicine, he entered the Institute of Physiology in the University of his native city, never to leave it permanently until his death.

Until the First World War he was mainly interested in problems of metabolism, especially in those of resorption, and one of his publications foreshadowed the insulin problem. He spent at that time practically all his summer vacations at some world centre of learning. On one such occasion, in New York, Jaques Loeb invited him to stay at the Rockefeller Institute, where they were working together on osmotic problems; but Kőrösy decided to return to Hungary, which proved fatal for his life and career.

During most part of the First World War and some time after, he was acting director of the Physiological Institute, shouldering an unusual load of teaching in difficult circumstances. Anti-semitic racial prejudice, rising quickly after the War, forced him from this position and practically stopped his experimental work. He turned to genetics and developed a mathematical theory of coupling between genes, published as a long monograph in German. During the last ten years of his life he cleared up important problems on crossing-over interference.

Political terror made him conscious of his Jewish duties, and he soon rose to the presidency of the Hungarian Pro-Palestina Association. The Nazis deported his younger son, who failed to return. The months of terror, the loss of access to his precious library and files, even after the War, hastened his death.

Prof. Kőrösy belonged to those men whose respect for truth and justice was embedded in a nature fond of beauty and full of humanitarian sentiment. He was a well-known figure at physiological congresses in Paris, Budapest, London, Boston, Leningrad, Venice, Edinburgh, and was loved for his kindly, gentle nature by friends and students the world over. Music was his favourite recreation, and he loved to travel, always taking his family with him. His wife, whom he married early in life, and three of his children, survive him.

M. POLANYI

WE regret to announce the following deaths:

Sir Wilfrid Grigson, C.S.I., sometime director-general of revenue in Hyderabad, author of "The Aboriginal Problem in the Central Provinces and Berar" and other anthropological studies, on November 26, aged fifty-two.

Dr. Louis Rapkine, director of the Department of Cell Chemistry, Pasteur Institute, Paris, on December 13.

Dr. Marjory Stephenson, M.B.E., F.R.S., of the Medical Research Council Unit for Chemical Microbiology, on December 12, aged sixty-two.

We are glad to learn from Prof. J. Heyrovský, of the Charles University, Prague, that Dr. F. Běhounek, whose death was announced in *Nature* of December 4, is alive and well.

NEWS and VIEWS

U.S. National Academy of Sciences: Agassiz Medal

THE National Academy of Sciences presented the Alexander Agassiz Gold Medal and honorarium for 1948 to Dr. Thomas Gordon Thompson at the autumn meeting of the Academy held at the University of California, Berkeley, on November 15. Dr. Thompson, professor of chemistry and director of the oceanographic laboratories of the University of Washington at Seattle and Friday Harbor in the State of Washington, has long been a leader in investigations of the complex chemistry of the ocean, with special attention to the waters of the north-east Pacific, Puget Sound, the San Juan Archipelago and the Bering and Chukchi Seas. Under his inspiration and leadership, his associates and students have devised and developed effective methods and techniques for the isolation and the quantitative determination of many of the elements and their compounds which occur in minute concentrations in sea water. Examples of such are iron, lithium, silicon, manganese, aluminium, boron and radium, the fluorides, phosphates and silicates, the isotopes of the elements of water and the dissolved gases, and the ionic ratios of the major constituents of sea water in various parts of the ocean. In organising the oceanographic laboratories at Seattle and Friday Harbor, Dr. Thompson brought together specialists in the fundamental sciences associated with the various departments of a great university, and directed their attention and stimulated their interest in the many problems presented by oceanic phenomena. Dr. Thompson has been chairman of various international committees, particularly the committee of the International Association of Physical Oceanography, appointed for the purpose of establishing standard units and procedures for the promotion of studies of the chemistry of the ocean. Established by Sir John Murray in 1911, the Alexander Agassiz Gold Medal is awarded by the Academy "for original contribution in the science of oceanography to scientific men in any part of the world".

William Davidson of Aberdeen: 1648

A TERCENTENARY Memorial Lecture entitled "William Davidson of Aberdeen: The First Scots Professor of Chemistry" was delivered in Marischal College, Aberdeen, on November 26, 1948, by Dr. John Read, professor of chemistry in the University of St. Andrews. Davidson was a native of Aberdeenshire who graduated at Marischal College in 1617 and then migrated to France. Here he became known as an authority on medicine, pharmacy and chemistry. He gave instruction in medical chemistry of the Paracelsian type, and was appointed a physician to the French king. In 1647 he was nominated to the first chair of chemistry to be founded in France, at the Jardin du Roi in Paris, where he entered upon his duties in 1648. Davidson was one of the three earliest occupants of a chair of chemistry, and the first native of the British Isles to become a professor of chemistry. Owing to religious and medical jealousies, he was forced to resign the chair in 1651; thenceforward, until 1667, he was chief physician to the King of Poland. He died in Paris in 1669. Besides various medical works, Davidson wrote an early text-book of chemistry entitled "Philosophia Pyrotechnica". Although imbued with the ideas of his alchemical predecessors, and given to associating the doctrines of chemistry with religious and metaphysical conceptions, he has claims to be called a chemist rather than an alchemist. Davidson was particularly proud of the blue blood of Scotland that ran in his veins; in 1629 he obtained a patent of nobility from Charles I and thereafter styled himself 'Nobilis Scotus'. To account for his entering the medical profession he told his readers that "professors of medicine were invested with such honour by the kings of Scotland that they enjoyed a title equal to that of earls".

U.S. Scientific Mission to Japan

THE Supreme Commander, Allied Powers ('SCAP') has announced that a United States scientific mission to Japan "is scheduled to arrive in that country on or about November 26 and may be expected to remain until about December 18, 1948". The mission is composed of five distinguished American men of science, selected by the National Academy of Sciences, and includes: Dr. Detlev W. Bronk, chairman of the National Research Council, foreign secretary of the National Academy of Sciences, and president-elect of Johns Hopkins University; Dr. E. C. Stakman, chief of the division of plant pathology and botany, University of Minnesota; Dr. Zay Jeffries, vice-president of the General Electric Company, and general manager of its chemical department; Dr. I. I. Rabi, professor of physics, Columbia University; Dr. Roger Adams, head of the department of chemistry, University of Illinois, and chairman of the scientific advisory group that visited Japan in 1947. Dr. Bronk is chairman of the present mission. The new mission is making the visit at a time when some forty thousand Japanese scientific workers, representing all fields of research, are participating in the election of 210 members for the country's first National Science Council. This election, due on December 20, is considered to be of unusual interest as it is thought to represent the first attempt of scientific workers of any country as a whole to elect members of its supreme scientific organ. The mission is expected to review progress made by Japanese men of science in the development of democratic national organisations for scientific activity. It is expected to bring up to date the report submitted by the previous advisory group; recommendations by that group served as guides to 'SCAP' sections in judging proposals of the Japanese for the reorganisation of national scientific bodies. The group proposes to spend approximately one day each in Sendai, Sapporo, Kyoto and Hiroshima; the remainder of the time will be spent in Tokyo in discussion with 'SCAP' personnel and Japanese scientific workers.

Vacation Work for Technical Students

THE fourteenth annual report for the year ending October 1948 by the Vacation Work Scheme of the Imperial College of Science and Technology has recently been published. The Scheme aims at providing work in Great Britain and abroad for students during their vacation, and it is almost entirely voluntary in nature. During 1948, 829 students participated as compared with 705 in 1947 (this increase being largely due to a greater number of overseas students); and this year's total was made up of 200 overseas students and 629 British, 194 of these latter having worked abroad. The bulk of the British students (591 in actual number) was drawn from the three Colleges which form the Imperial College, namely, the Royal College of Science, Royal School of Mines, and City and Guilds College. In January 1948 an international conference was held in London at the Imperial College to unify the procedure and minimize the correspondence for the exchange of students between different States; ten countries sent representatives and an organisation was founded called the International Association for the Exchange of Students for Technical Experience. During the recent summer vacation this Association has successfully exchanged 950–1,000 students between the participating countries. The next conference of this Association will be held in Copenhagen during January 3–7, 1949. As a result of the establishment of this Association, central organisations have been set up in each country; the governors of the Imperial College have decided to broaden their machinery, coping with international exchange, to include undergraduates from other universities and colleges in Great Britain, and this information has already been communicated. The aim is to make the scheme self-supporting, if possible, through an affiliation fee payable by each college concerned (based on the number of students sent abroad) together with a registration fee payable by the student. Offers of financial assistance have already been made by Messrs. Lever Brothers and Unilever, Ltd., Rolls Royce, Ltd., and the National Oil Refineries, Ltd., and it is anticipated that the scheme will be in operation for the summer of 1949.

Management Abstracts

FOR these days, *Management Abstracts*, the first issue of a series of specialized publications dealing with the different aspects of management to be published by the British Institute of Management (London), seems rather a lavish production. It covers some two hundred British and Overseas publications dealing with current developments in management science, and the abstracts are classified under such headings as general management and organisation; works management; personnel and welfare; financial management; distribution; supplies; transport; statistics; public administration; education and training. *Management Abstracts* will be issued monthly and is intended to cover, eventually, material published in any part of the world; but on its present scale such cover can scarcely be obtained without very considerable expansion on the first two issues. The basis of selection of the abstracts is not apparent, although the more important articles published in Great Britain in recent months appear to be included. For the annual subscription of 30*s*. (or 3*s*. per copy) the business executive may, as it is claimed, save some time; but the production is unlikely to give him much that he cannot readily obtain, and probably earlier, from an efficient firm's library. The publication also includes "Book Notes", which are brief and mainly descriptive. This section might perhaps be expanded with advantage and the length of the abstracts curtailed, particularly if the latter were made purely descriptive and not, as in these two issues, in part critical.

Milk: from Cow to Consumer

WALLACE PRODUCTIONS, LTD., have just finished making a documentary film for the United Dairies, Ltd. This film, which lasts for about half an hour, is called "The Milky Way" and was shown to a small invited audience on November 30 at the British Council Theatre in London. It tells the story of the production, pasteurization and distribution of milk under modern conditions with particular reference to London (the United Dairies, Ltd., being one of the major suppliers of milk in the London area); but the theme is representative of any large town or city where rigid precautions are taken with regard to the safety and purity of milk. The general scientific level of the film has been designed for showing to student-nurses and the senior science forms of secondary schools; but it can be recommended to any intelligent person, scientific or otherwise. The emphasis stressed throughout is on hygiene; but the full account of milk from cow to consumer is amply and well told. The makers and sponsors of this documentary film are to be congratulated on a production which has entertainment value as well as scientific and educational interest.

Information Services Committee

ARISING out of the Scientific Information Conference held last June, the Council of the Royal Society has set up a Standing Committee on Information Services. The terms of reference are: (1) to advise on means of improving existing methods of publishing, abstracting, indexing and distributing scientific information and, in particular, to advise on the implementation of the recommendations of the Royal Society Scientific Information Conference; (2) to report to the Council of the Royal Society.

The following have agreed to serve on the committee: Sir Alfred Egerton (*chairman*); the Treasurer and the Secretaries of the Royal Society; Dr. T. E. Allibone; Prof. J. D. Bernal; Dr. G. L. Brown; Sir David Chadwick; Mr. J. E. Cummins; Dr. G. M. Findlay; Dr. J. E. Holmstrom; Dr. A. King; Dr. J. G. Malloch; and Dr. C. F. A. Pantin.

Colonial Service: Recent Appointments

THE following appointments in the Colonial Service have been announced: J. S. Campbell, agricultural officer, Nigeria; W. Galley, agricultural officer, Uganda; W. Smith, agricultural officer, Gold Coast; E. A. Edmonds, geologist, Gold Coast; N. J. Guest, geologist, Tanganyika; K. Taylor, geologist, Uganda; R. B. Smith, agricultural officer, Trinidad; J. H. Wheelan, assistant conservator of forests, Gold Coast; J. D. Farquhar (assistant conservator of forests, Palestine), assistant conservator of forests, Tanganyika; R. B. McConnell (geologist, Tanganyika), senior geologist, Nigeria. The following have been appointed assistant conservators of forests in the countries mentioned: M. F. H. Abraham (Kenya), M. C. Argyle (Kenya), J. H. Blower (Tanganyika), W. Carmichael (Tanganyika), D. M. Duggie (Gold Coast), W. G. Dyson (Kenya), C. A. Walker (Nigeria), F. Weston (Uganda).

Lectures on Manufactured Foods

THE Nutrition Panel of the Food Group of the Society of Chemical Industry is arranging a series of meetings for discussing the problems affecting manufactured foods in Great Britain. Sausages, soups, ice-creams, cake mixtures, jam, processed cheeses, and the like, form an important part of present-day dietary; but there is still much to be learned about their nutritional significance. The first meeting of this series will be held on Wednesday, January 5, 1949, at Gas Industry House, 1 Grosvenor Place, London, S.W.1, at 6.30 p.m., and the subject will be "The Sausage as Food". The speakers will include Mr. H. P. Blunt, of the Ministry of Food, on "The History of Sausages"; Mr. Osman Jones and Mr. M. G. Read, on the composition of fresh and processed sausages respectively; and Dr. Magnus Pyke on "Sausages and Nutrition".

University of Glasgow

PROF. C. M. YONGE has been re-appointed a director of the Scottish Marine Biological Association. Dr. Angus Macphail has been appointed lecturer in public health, and Dr. W. G. A. Begg an assistant in anatomy. Mr. John Green has resigned from the Departments of Biochemistry and Medicine to become lecturer in clinical chemistry in the University of Aberdeen, and Dr. J. D. Morrison from the Department of Chemistry to take up a post with the Council for Scientific and Industrial Research at Melbourne. Mr. J. C. Gunn, of the Department of Mathematics, University College, London, has been appointed to the Cargill chair of natural philosophy in succession to Prof. T. Alty.

For the current session 266 students have been admitted into the Faculty of Pure Science. Some 144 research students have been registered, including fifty working in the Royal Technical College, nine at the Hannah Institute and three at the Agricultural College.

Announcements

THE Medal of the Royal Society of New South Wales has been awarded to Prof. W. L. Waterhouse, research professor of plant pathology and agricultural botany in the University of Sydney. The award is made for meritorious contributions to the advancement of science: this may include administration and organisation of scientific endeavour. The citation states that this year's award is made to Prof. Waterhouse in recognition of his services to the Society and his valuable contributions to the field agricultural science, particularly with regard t research on cereals.

PROF. R. E. MORTIMER WHEELER, professor archæology in the University of London, formerl director-general of archæology in India, will serve adviser to the Government of Pakistan in setting u a department for the exploration and preservation ancient sites and in forming a museum at Karachi.

PROF. LINDSAY TASMAN RIDE has been appointe vice-chancellor of the University of Hong Kong. A an Australian Rhodes Scholar he graduated i medicine at Oxford, and has been professor physiology at the University of Hong Kong sinc 1928. Prof. Ride had an active military career i China during the Second World War, since when h has been in command of the Hong Kong Volunte Defence Force.

DR. E. J. BOORMAN has been appointed chi chemist of the Anglo-American Oil Co., Ltd. Aft postgraduate research at the Imperial College Science and Technology, London, Dr. Boorma entered the Department of the Government Chemis where he was concerned with petroleum product Soon after the end of the War he joined the staff Esso Development Co., Ltd.

DR. ARTHUR J. BIRCH, of the Dyson Perri Laboratory, Oxford, has been appointed Smithso research fellow of the Royal Society for four yea from January 1, 1949. The fellowship is tenable the University of Cambridge, where Dr. Birch wi continue his researches in organic chemistry.

THE following appointments have been made i the University of London: Dr. B. J. Lloyd-Evan to the Kennedy chair of mechanical engineerin tenable at University College; Dr. W. F. Jepson, t the University readership in applied entomolog tenable at the Imperial College of Science an Technology.

A PROOF copy of Prof. Geitler's revision of th Cyanophyceæ in the "Natürliche Pflanzenfamilien (1 *b*, 1942), most of the copies of which were destroye during the War, has been sent by the author to Pro F. E. Fritsch (at the Botany School, Cambridge). will be loaned for short periods to anyone who interested on application to him.

THE Rationalist Press Association has arrange a course of six lectures under the general title "Intuition and Reason" to be delivered by D Maurice Burton. The lectures will be given eac Monday during January 17–February 21, 1949, the Alliance Hall, Palmer Street, Westminster, Lo don. Tickets for the course cost 12*s*. (9*s*. for R.P. members), and may be obtained from the Rationali Press Association, Ltd., 4–6 Johnson's Court, Fle Street, London, E.C.4.

THE Institution of Naval Architects is offering th Martell Scholarship in Naval Architecture, to be hel at one of the following institutions: Universities Glasgow, Durham (King's College, Newcastle-o Tyne), or Liverpool, or the Royal Naval Colleg Greenwich. It is tenable for three or four years and annual value £175. It is open to British apprentices pupils, less than twenty-three years old, in the roy dockyards or private shipyards. Entries close January 15; full particulars can be obtained from th Secretary, Institution of Naval Architects, 10 Upp Belgrave Street, London, S.W.1.

Method for Obtaining Wool Roots for Histochemical Examination

A USEFUL technique has been developed for obtaining moderately large samples of wool roots for histochemical examination. It is hoped that this technique will assist in elucidating the mode of formation of the wool fibre and also facilitate investigations already in progress in this laboratory, which are concerned with developing methods for removal of wool from sheepskins.

Fig. 1

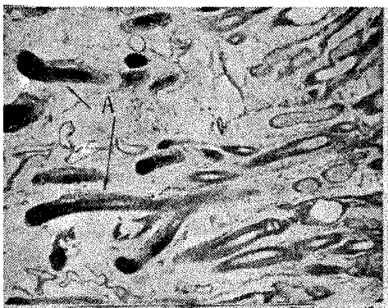

Fig. 2

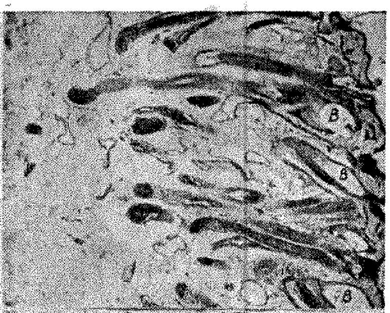

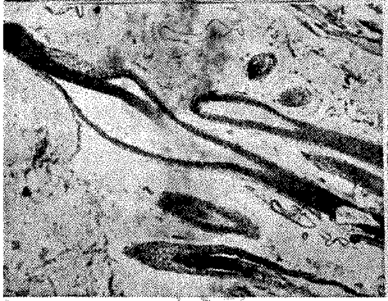

Fig. 3

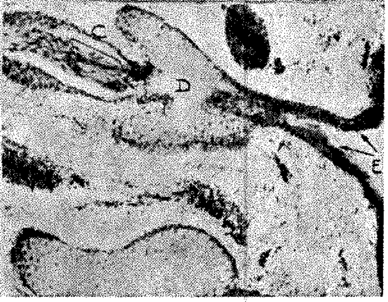

Fig. 4

Formerly, it was possible, by tedious dissection of)ulled staples of wool, to obtain a few milligrams of vool roots; by the new method 0·5–1·0 gm. can)e collected with little effort.

A piece of sheepskin approximately 500 sq. cm. s cut from a fresh skin, most of the wool removed vith scissors, and the remainder clipped to within -3 mm. of the skin. The skin is then placed flat, vith flesh side down, on a piece of plate-glass. A eeswax–rosin mixture (2 : 7 by weight) at about 0° C. is then run over the surface of the skin to a hickness of about 5 mm. When the wax has set, t is lifted with the adhering skin from the glass and he skin peeled away from it gradually, leaving a vax sheet with the wool fibres firmly embedded in t and with the roots exposed. The roots can be arvested readily by clipping with an electric razor, r preferably with a fine animal-hair clipper. The lipping must be done carefully to avoid contamination with particles of wax. By this method it is ossible to obtain material which is all of subpidermal origin.

To ascertain the nature of the tissue thus obtained, sections of the skin have been made before and after removal of the roots. The results of this examination are recorded in the accompanying photomicrographs.

A section of skin is shown in Fig. 1 with the wool roots intact and visible at points marked *A*. In Fig. 2 is seen a section of the same skin after removal of the fibres. Some tissue breakdown is evident; but the lining epithelium and the basal cells are for the most part intact. The vascular areas shown at *B* are probably artefacts and may be due to the removal of sudoriferous glands during sectioning. In Fig. 3 a complete root with shaft is seen *in situ*. The open area around the fibre is, no doubt, an artefact; but it does indicate that there is no strong attachment of the fibre to the follicle lining around the zone of keratinization. Fig. 4 shows the effect of removal of the root on the neighbouring structures. Derangement of the epithelium is evident at *C*; but, as shown at *D*, little or no sebaceous gland tissue has been removed, and the epidermis at *E* is intact.

The yield of roots from the wax sheets is affected by the depth of the root in the skin, and from measurements made on a number of different skins it was found that, whereas a root-length of 0·7–0·8 mm. yielded only 10–20 mgm. per 100 sq. cm. skin, a root length of 1·2–1·3 mm. yielded 200–300 mgm. per 100 sq. cm. skin. If the wool roots are too short for clipping, root extract can be obtained by applying a suitable extractant to the wax sheet and brushing it over the surface.

Roots have been obtained by the same technique from guinea pig skin, and no doubt the method is applicable to any type of skin.

Thanks are due to Miss H. M. Matthews for technical assistance.

Fine Structure of Cell Walls in Fresh Plant Tissues

THE increasing preoccupation of plant physiological laboratories throughout the world with problems of growth makes it very desirable that the details of structure in the cell wall, in growing tissue, should be known as completely as possible in the condition occurring in the living tissue itself. A good deal of the discussion arising from growth studies centres around the configuration of the cell wall, and the facile generalization of the striking results of X-ray analysis in dried material to cover the condition in fresh

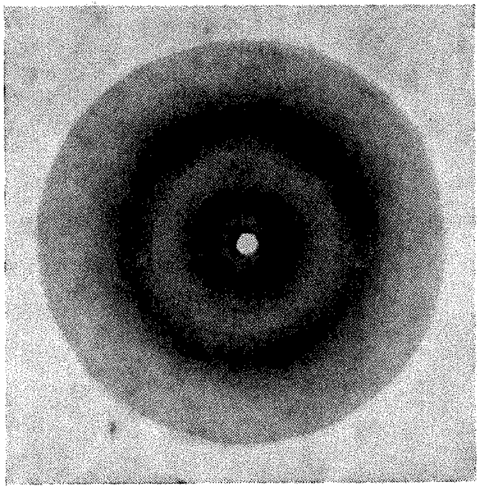

Fig. 1. X-ray diagram of a bundle of parallel filaments of *Rhizoclonium*, beam perpendicular to filament-length. The alga was put in the spectrometer straight from the culture vessel and kept running with water during the exposure. Exposure time 10·5 hr. Note that in addition to the two water haloes there is a diagram of cellulose identical with, though weaker than, that of the dried specimen in Fig. 2

tissue is perhaps not *a priori* legitimate; for it is highly improbable that the dried material, even when rewetted, can be considered with any exactitude as equivalent to the original material fresh from the plant. In point of fact, attention was directed some years ago to the implications of the fact that in bacterial cellulose the planes of 6·1 A.-spacing lie parallel to the surface of the cellulose plate only after drying[1], so that the demonstration of the special orientation of dried walls of *Valonia*[2] and *Cladophora*[3] did not necessarily guarantee a similar orientation in fresh material.

It should, however, be noted that the drying of bacterial cellulose might involve nothing more than a packing of flat plates (from the bacterial capsules) flat on the substrate, and the orientation might, in fact, be present in each plate even in the fresh cellulose.

More recently even the existence of crystalline regions in fresh material has been called into question[4]. It is observed that when fresh cotton hairs are photographed without drying, then the diagram shows merely the water haloes with no sign of a cellulose diagram; this latter appears only after the specimen has dried, but remains present on rewetting.

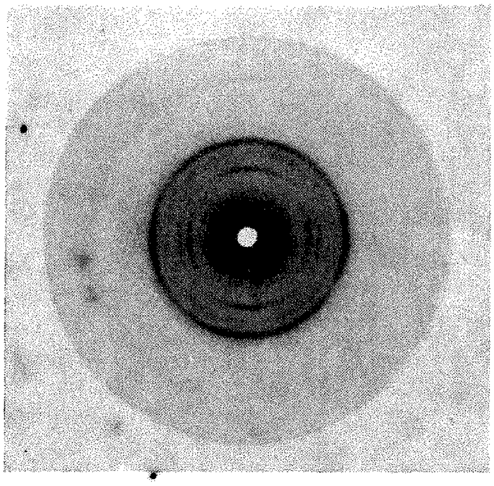

Fig. 2. The same bundle of filaments after drying. The photograph is much stronger but otherwise is identical with the cellulose diagram of Fig. 1

Correspondingly, Berkeley and Kerr regard the cellulose in cotton hairs as existing in the form of single, parallel cellulose chains separated by water molecules. It seemed to us that there were other, more probable, interpretations of these results. First, the water halo in fresh cotton is very intense and could possibly mask the cellulose diagram, the intensity of which might well be reduced by the absorption of X-rays by the water and by an angular dispersion of the crystalline regions caused by the presence of the water between them. Rewetting of dried specimens would not produce the same effects since it is well known that dried cellulose has a lower regain than fresh material, and in any event the lumina do not refill once the cells have dried.

We therefore decided to re-examine the condition of fresh material both for the existence of micelles and for special orientation, and therefore chose as our material an alga, *Rhizoclonium*, which will tolerate abundant water during the exposure in an X-ray spectrometer, and cambial tissue from *Pinus sylvestris* as an example of a rapidly growing tissue.

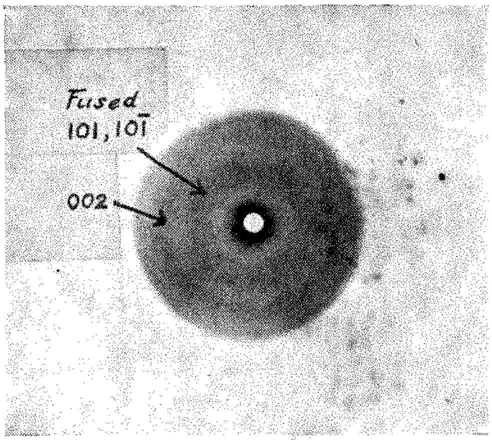

Fig. 3. X-ray diagram of a pellet of fresh cambial tissue maintained in equilibrium with air at 94 per cent relative humidity during the exposure. The 002 and fused 101 and $10\bar{1}$ circles are clearly visible

Both were collected fresh and kept wet during exposure, except that with cambial tissue the water halo had to be reduced in intensity by mounting the tissue in a holder within which the air was maintained at 98 per cent relative humidity. The tissues were then allowed to dry, and X-ray diagrams were taken of this dried material. The resulting photographs are presented in Figs. 1, 2, 3 and 4.

In comparing the two algal photographs it should be remembered that a reduction of apparent intensity in the cellulose diagram of wet material is to be expected both on account of the intense background and of the absorption of X-rays by water. Intensity differences can therefore at the moment be disregarded. In the wet specimen (Fig. 1) the arcs of the cellulose diagram are very apparent and are as sharp as those in the dry material. Further, the disposition of the arcs is the same, and in particular the 6·1 A.-arc is missing along the meridian. Thus in this material, which had never been dried, not only is the cellulose organised into micelles, but also these in turn have already the special orientation

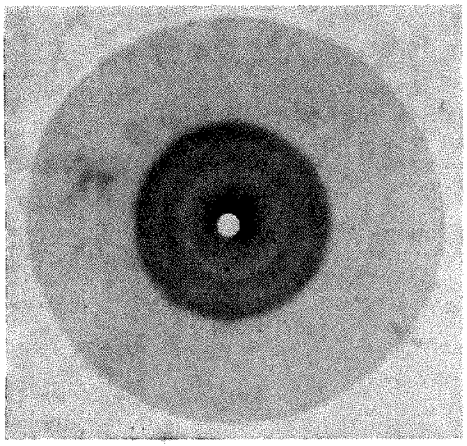

Fig. 4. Comparable photographs of a pellet of dried cambium

demonstrated in dried cells. In cambium, too (Fig. 3), the 3·9 A.-ring and the fused 5·4 and 6·1 can plainly be identified so that here, too, micelles exist in fresh tissue, much as they do in dry material (Fig. 4). In point of fact, it is probable that the 6·1 A. (101) arc is missing in untreated cambium. This point will be discussed elsewhere; it is not of importance to the present discussion, and the inner ring in the cambium diagrams is therefore treated conventionally as a fused 101, 10$\bar{1}$. It is not, of course, clear that the size of the micelles is the same in wet as in dried tissue; but it is certain that in the materials we have used, crystalline regions do exist sufficiently extensive to give rise to X-ray diagrams.

It is therefore reasonably certain that consideration of growth processes in plant cells will need to continue to be made in terms of wall structure substantially similar to that described for dried material.

The senior author is indebted to the Department of Scientific and Industrial Research for a grant to cover in part the expenses of the algal research, from the programme of which some of the present results are drawn.

Extraction of Bright Coals by Anhydrous Ethylene Diamine

PYRIDINE has long been known as a good solvent for coal[1]. It is effective even at room temperature, and causes marked swelling of the coal substance. Solutions are usually prepared at the boiling point and are recognized to be at least predominantly colloidal. It has recently been found that ethylene diamine is a more rapid and in some respects more powerful solvent, its action being similar in many ways to that of pyridine. A preliminary survey has been made of its interaction with coals. As with pyridine[2], the action of ethylene diamine is retarded by the presence of moisture; commercial diamine containing 40 per cent water has very little effect at room temperature. The solvent used in this work contained less than 1 per cent water.

The process of solution of lower-rank bituminous coals is accompanied by great swelling of the solid and a large heat evolution. Dried pieces of whatever size imbibe finally about 1·2 gm. of diamine per gm. of coal. Irreversible adsorption of the solvent is observed on both residue and recovered extract; when, by a nitrogen balance, allowance is made for this, the total yield of solid products agrees closely with the weight of original coal. The extract solutions have been studied by optical and other methods and found to consist largely of colloidal particles of the order of hundreds of angströms in diameter, together with a background of somewhat smaller material (I am indebted to Dr. L. Kann of these laboratories for this information). The evidence to date does not preclude the presence of small molecules in addition; but the quantity in this form is certainly not great. Osmotic measurements (for example, vapour-pressure lowering) are unreliable because a very small quantity of ammonia is slowly but continuously evolved by coal in contact with ethylene diamine. (The source of the ammonia has not been established; in view of the small quantity produced, and the readiness with which ethylene diamine liberates ammonia on treatment with other substances, its formation may be adventitious.) In many cases, unlike the behaviour of pyridine-coal sols, the solution of extract in the original solvent continues to form a stable colloidal solution when poured into water, although it can readily be flocculated by addition of acid or of multivalent cations. The particles in aqueous solution (at pH $\sim$ 11·5) are negatively charged.

Higher rank (coking and steam) coals yield very much less extract than those of lower rank and show a much smaller degree of swelling. After 48 hours treatment in a Soxhlet apparatus containing nitrogen at atmospheric pressure, typical yields of extract, corrected for solvent, are: coals containing less than 85 per cent carbon (Parr pure coal basis), 35–40 per cent; coals containing more than 88 per cent carbon, 1–5 per cent. Anthracite is not visibly affected and yields no extract. Bovey Tracey lignite yields, in a Soxhlet apparatus, about the same proportion of extract as a low-rank bituminous coal; at room temperature the yield of extract is relatively smaller, though the swelling is much the same as with the coal. 'Humic acids' produced by oxidation of coal and purified by extraction with, and re-precipitation from, an organic solvent dissolve only to a limited extent in ethylene diamine even at the boiling point; on addition of water, however, they dissolve rapidly and completely just as in 10 per cent aqueous sodium hydroxide. Irish dopplerite swells considerably but very slowly in ethylene diamine, and very little extraction (as indicated by colour) takes place even on boiling; it is rather more soluble when water is added. The same sample of dopplerite was only slightly soluble in 10 per cent sodium hydroxide. Spruce lignin (for which I am indebted to Dr. W. G. Campbell, of the Forest Products Research Laboratory, Princes Risborough) and cellulose both swell in ethylene diamine, but yield no appreciable soluble material.

The degree of extraction at room temperature varies in an interesting manner with solvent/coal ratio, successive treatment of the same material, and coal rank. This will form the subject of a further communication. It may be mentioned here, however, that at room temperature the degree of extraction of low-rank coals rapidly approaches a limit (about 10 per cent) as the solvent/coal ratio is increased ; if the sol is then removed by filtration and fresh solvent is added, a further substantial amount of extract (about 5 per cent) is obtained. This can be repeated many times before the amount of extract becomes negligible.

It is now well recognized that coal has a colloidal structure[3]. The type of extraction phenomenon outlined in the last paragraph is characteristic of colloidal systems, although the present case appears to have some unusual features. Swelling in solvents is a normal property of colloidal substances, including polymers. In the case of coal, a thermodynamic treatment must take into account the distribution of colloidal material in appreciable concentration between both phases.

Properties of Ethylene Diamine

THE properties of ethylene diamine have been summarized by Wilson[1] and by Putnam and Kobe[2]. In the course of recent work with this substance, additional and in part contradictory information has been obtained.

Samples of commercial anhydrous ethylene diamine were refluxed with metallic potassium until the liquid became permanently dark-coloured ; it was then distilled, and redistilled to check the boiling point. At 20° C. the viscosity was found to be 1·52 cp., the density 0·893 gm./c.c. These values are rather lower than previous determinations. The kinematic viscosity is very sensitive to small quantities of water and of carbon dioxide, and its measurement has been found convenient as a rapid test for purity. A striking maximum ($\sim$ 12·7 cp.) occurs in the curve relating dynamic viscosity to water content, at a molecular proportion of approximately 1 diamine : 2 water. The refractive index is not sensibly altered by addition of up to 3 per cent by weight of water. It has also been found that the point of half-neutralization in the potentiometric titration curve can readily be detected, but is not sharp enough to be used for the accurate analysis of ethylene diamine–ammonia mixtures.

The anhydrous diamine is miscible in all proportions not only with water, but also with lower alcohols, ethers and ketones, chloro-methanes and lower benzene homologues. Addition of 2–4 per cent of water by volume has been found to effect sensibly complete separation of ethylene diamine from solution in such liquids as xylene and ether ; it is probable that earlier reports of its limited solubility in some of the above solvents have arisen from the use of insufficiently dried diamine.

Diamine is immiscible with paraffins unless a third component, such as alcohol or chloroform, is added.

So far as we are aware, the unpleasant temporary physiological discomforts which can be caused by ethylene diamine are not well known. The liquid if not washed from the skin causes blistering. One of the authors appears to be allergic to the fumes even in low concentration. The symptoms (acute fits of coughing some hours after exposure) did not in the first instance develop for some weeks.

Solubility of Bituminous Coal in Alcoholic Potash

IN the course of some exploratory experiments carried out eighteen months ago when I was a member of the staff of the British Coal Utilisation Research Association, it was observed that appreciable quantities of some bituminous coals were soluble (or dispersible) in alcoholic potash. A Northumberland coal containing 82·6 per cent of carbon and 5·1 per cent of hydrogen (on ash-free basis) was soluble to the extent of 20 per cent. Since its solubility in aqueous potash was quite inappreciable, this coal contained no significant quantity of ulmic material ('humic acids'), such as is formed when coal is oxidized by air exposure. Moreover, the proportion of coal extracted by alcoholic potash at the boiling temperature was unchanged when the experiment was carried out in the complete absence of air.

The extracted material remained dissolved (or dispersed) on diluting the alcoholic solution with water, but—like the so-called 'humic acids' obtained by the slow oxidation of coal—was immediately flocculated to a brown powder on addition of dilute acid. The elementary composition of this material was close to that of the parent coal (both being reduced to the pure coal basis), but it contained a somewhat higher proportion of oxygen (determined 'by difference').

The presence of small quantities of water in the alcohol (or the coal) slowed down the rate of extraction somewhat, but appeared to have but little influence on the proportion of extract finally obtained.

In further experiments the same parent coal was first separated into α-(pyridine-insoluble), β-(pyridine-soluble, chloroform-insoluble) and γ-(chloroform-soluble) fractions. The γ-fraction was found to be almost completely soluble in hot alcoholic potash, the β-fraction soluble to the extent of *c.* 50 per cent and a small portion of the α-fraction was also soluble. The extracts from all three fractions were similar in their behaviour.

A South Wales 'coking' coal (containing 89·7 per cent carbon and 5·0 per cent hydrogen on the ash-free basis) was soluble only to the extent of about 5 per cent in alcoholic potash. The extract showed similar behaviour to that from the Northumberland coal. While these experiments with only two coals afford insufficient data for generalization, a decreasing degree of solubility with increase of rank is for several reasons to be expected.

One possible interpretation of the behaviour described is that the alcoholic potash effects an ester hydrolysis, and that part of the coal substance consists of 'humic humates'.

Membrane Electrophoresis in Relation to Bioelectrical Polarization Effects

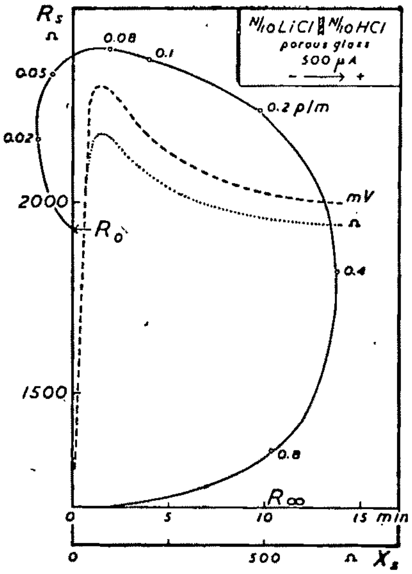
IN electrophysiology the term 'polarization' often has an ambiguous meaning. Here it will be used in the physical sense as an overall definition to include changes in the 'resting potential' of the object (membrane, nerve, skin, etc.), as well as the appearance of rectification, capacity and inductivity effects under the influence of an externally applied current. The potential changes and the rectification effects have mostly been interpreted in a qualitative manner in terms of selective ion permeability, and the capacity as 'double layers', 'dielectrics', etc.[1,2,3]. Cole[4] has recently made the unexpected observation of an inductance component in the squid axon, which he seems inclined to explain as analogous to piezo-electric behaviour. Lorente de Nó[5] prefers more unspecific concepts implying also chemical reactions.

A very simple system, which can display the characteristic features of polarization, is:

Homogeneous mass (1)	Porous membrane	Homogeneous mass (2)
A^+R^-	$A^+R^- + B^+R^-$	B^+R^-

If the mobility of the ion constituent B^+ is greater than that of A^+, then the application of direct current, with the direction (1) anode and (2) cathode, will decrease the conductivity within the membrane. A reversed current direction will increase it; thus the 'rectification' may be easy enough to understand. The membrane behaves as a non-linear circuit element. Obviously this type of electrolyte system is closely related to the well-known 'moving boundary' systems. Theories[6-11] and experiments[12,13] show that the transition layer between masses (1) and (2) under appropriate conditions can be segregated in successive layers with different ionic compositions, which can *move* in either direction. These concepts can easily make understandable the fact that a membrane, supporting electrolytes, can change its longitudinal conductivity in a non-linear fashion. A great variety of patterns of the interrelations between direction, density and duration of the applied current and the resulting conductivity can be anticipated. The changes of the conductivity (and membrane potential proper) may lead to voltage *vs.* time curves similar to those known from the transient responses on rectangular D.C. pulses, applied to circuits containing resistances, capacities and inductivities.

The accompanying graph provides an example taken from a preliminary study. A system 0·1 *N* lithium chloride (stirred)/porous glass membrane/ 0·1 *N* hydrochloric acid (stirred) was subject to constant current flow with the cathode on the hydrochloric acid side. The change of the total membrane voltage with time exhibits an 'overshooting' (see the dashed curve, *mV*) well known from certain RLC (or RC) circuits. The parallel course of the high-frequency resistance of the membrane layer (dotted curve, Ω) indicates that the temporal variation of the potential is, in the main, caused by changes of the electrolyte content within the membrane (the membrane potential proper, that is, the 'back-E.M.F.', plays a minor part here). The voltage-time curve has also been transformed into an A.C. 'impedance locus diagram' by the aid of 'square wave analysis'[14]. The locus curve (full line) of the impedance at different A.C. frequencies is of the shape regarded as typical for a resistance–capacitance–inductance circuit (cf. ref. 15).



In conclusion, it may be stated that a purely aqueous electrolyte system may exhibit effects formally similar to rectification, capacity and inductivity. Changes of the 'resting potential' or 'back E.M.F.' can also be demonstrated, especially with charged membranes. All phenomena are due to ionic redistributions within the membrane, initiated by the flowing current. These observations may have bearings on discussions on the nature of biological polarization phenomena. More experimentation under well-controlled conditions seems desirable. Theories of electrolytic migration also require extension to include the effects of diffusion, membrane dimension, membrane charge, solvent movement, etc. Investigations in these directions are being made in this laboratory.

This type of moving-boundary can obviously be utilized as an electrophoresis method for separation purposes, particularly if a superposed counter-flow of the solvent is employed.

An extended report of this work will be published elsewhere.

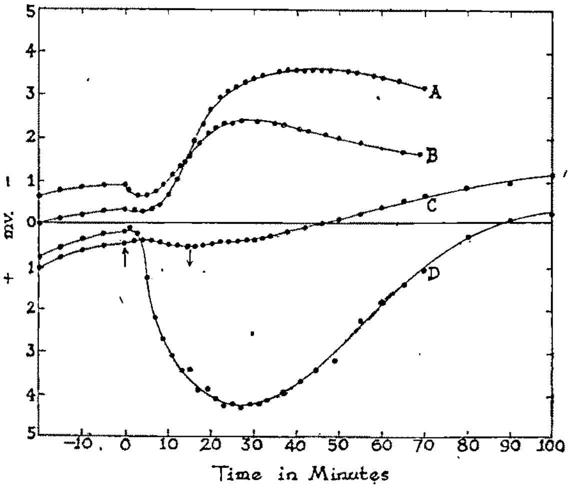
Electrical Potential Change Accompanying the Development of Rigor in Iodoacetate-Poisoned Muscle

No *a priori* answer can be given to the question whether the development of rigor in muscle poisoned by iodoacetate is accompanied by electrical depolarization, though it may be expected that the muscle after developing rigor will eventually become depolarized. The present work was an attempt to find an experimental answer to this question.

The sartorius muscle of the toad prepared with its nerve for stimulation was employed. The preparation was poisoned by soaking for 30–60 min. in 1/10,000–1/20,000 iodoacetate solution, sometimes with the addition of sodium cyanide to the concentration of $M/1,000$–2,000. Rigor of the poisoned muscle was induced in the usual way by stimulation, at the rate of one shock every 5 sec. in most experiments. A rough indication that the development of rigor was not accompanied by any considerable depolarization was first obtained by showing that the muscle, soon after the development of rigor, gave demarcation potential of the usual magnitude on crushing or on application of isotonic potassium chloride.



Time-course of electrical potential change of poisoned half of muscle relative to normal half. Stimulation, one shock every 5 sec. between arrows. See text for other explanation

A closer examination was then made by poisoning one half of the muscle and measuring the potential of this half against the normal half at short intervals during and after the onset of rigor. In such experiments the muscle was naturally mounted in air and the results regularly showed a slowly developing depolarization, beginning shortly after the start of stimulation and reaching a maximum in 30–40 min., roughly paralleling the course of the development of rigor. Both the course and the magnitude of the depolarization, however, depended on the temperature. The results of an experiment at 10–11° C. are reproduced in the accompanying graph, curves *A* and *B*, given by two symmetrical muscles. A comparison of pairs of curves such as these revealed the influence of an apparently insignificant difference in the experimental condition. When two strands of cotton-wool were used for connecting the muscle to the calomel half-cells used as leads (curve *A*), the depolarization was regularly greater than when two troughs about 8 mm. wide filled with Ringer solution served as contacts (curve *B*). The only obvious difference was that, if there was anything liberated by the muscle, it would be partially washed away from the segments of the muscle lying on the troughs.

We therefore tested the effect of deliberate washing. It was found that the depolarization of the poisoned half relative to the normal half observed when the muscle was mounted and stimulated in air disappeared more or less completely when the whole muscle was afterwards washed in stirred normal Ringer solution. We then attempted to determine the time-course of the electrical potential change accompanying the development of rigor while the whole muscle, one half of which was previously poisoned, was continually washed except during the short times required for potential measurements. Curve *C* represents the result when the washing solution was normal Ringer. It is seen that the depolarization of the poisoned half normally occurring during the first 30–40 min. after the beginning of stimulation was completely suppressed.

There is thus a strong indication that the initial depolarization accompanying the development of rigor was due to the release of some depolarizing substance by the muscle when developing rigor. In all probability this substance was potassium. Dean[1] has previously reported that iodoacetate-poisoned muscle, after the onset of rigor, lost a large amount of potassium. The use of potassium-free Ringer solution as a possibly more efficient washing solution then suggested itself, and the result was as shown in curve *D*, the two curves *C* and *D* being given by a symmetrical pair of muscles at 23° C. treated in identical manner except for the composition of the washing solution, and therefore directly comparable.

It is seen that, under the conditions of continuous washing with potassium-free Ringer solution, the initial phase of depolarization may be not only completely suppressed, but even actually replaced by a phase of large positive variation. That the half of the muscle subjected to rigor under these conditions contained less potassium than the normal half had been ascertained by separate potassium analysis of the two halves. A mere smaller potassium content of that half, however, could not account for its relative positivity. We had soaked half the muscle in potassium-free Ringer solution overnight, and then washed the whole muscle in potassium-free Ringer for half to one hour. The end which had previously been soaked in potassium-free Ringer solution overnight, while containing less potassium as afterwards determined by analysis, showed no relative positivity.

It may be concluded that when secondary change resulting from the release of potassium is eliminated, the development of rigor in iodoacetate-poisoned muscle is not accompanied by depolarization. Indeed, the primary event might even be an increase of polarization.

Nervous Mechanism in Tunicata

DESPITE the contributions of Lorleberg[1], Hilton[2], Hecht[3], Cate[4], Bacq[5] and Das[6], the picture of tunicate nervous relations is still incomplete. Although the central nervous system consists of only one compact intersiphonal ganglion and the peripheral system of a few nerves emanating from the former, the extreme sensitivity of monascidians to touch, vibrations, etc., is astounding. A person walking about in a room where expanded *Ciona*, *Ascidiella*, or *Styelopsis* are lying in a jar on a table is enough to make some of the ascidians contract. Lorleberg[1] stated that *Styelopsis* had free nerve terminations, whereas Das[6] found in *Herdmania* an extensive nerve supply, not only to the organs lying inside the mantle, but also to receptor cells of the test as well. I have now found these nerve fibres, ramifying into the mantle, the test, and ending in the receptor organs, in *Ciona*, *Ascidiella* as well as *Styelopsis*. Free nerve terminations have been found in *Styelopsis* and *Ascidiella* and probably occur in all Tunicata.

The nerves arising from the intersiphonal ganglion have both afferent and efferent fibres in them; and as they branch and subdivide to supply the muscles and the receptors, the afferent and efferent fibrils are separated to form the peripheral nerves. It has also been established that, in crossed reflexes, nerve impulses pass directly from one siphon to the other by way of the ganglion. Removal of the ganglion not only prevents crossed reflexes but also affects the threshold of sensitivity and rate of recovery.

A complete account of the nervous mechanism in the Tunicata is being published elsewhere.

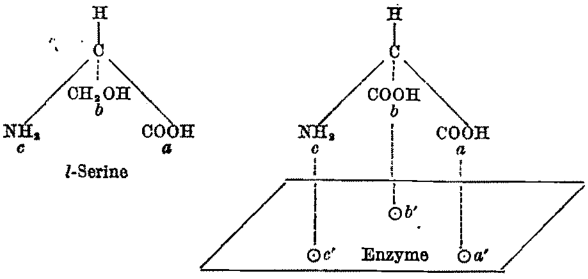
Interpretation of Experiments on Metabolic Processes, using Isotopic Tracer Elements

IN two instances, the distribution of isotopic carbon in the product of a metabolic process has been used to infer that a symmetrical intermediate compound is not involved. Wood *et al.*[1] showed that isotopic carbon, introduced as carbon dioxide together with pyruvate, led to the formation of ketoglutarate which contained isotopic carbon only in the carboxy group next to the keto group; on these grounds, they excluded citrate as an intermediate. Shemin[2] found that when glycine is formed from serine, containing isotopic nitrogen and isotopic carbon in its carboxy group, the relative abundance of nitrogen-15 and carbon-13 in the glycine was the same as in the serine; he argued that amino-malonic acid is therefore not an intermediate in this process.

These conclusions seem to arise from the fallacy that, because symmetrical products arising from the *d*- or *l*-form of an optically active precursor cannot be distinguished, therefore the two identical groups of a symmetrical product formed from one optical antipode cannot be distinguished. On the contrary, it is possible that an asymmetric enzyme which attacks a symmetrical compound can distinguish between its identical groups. This power of distinction is illustrated for the case of amino-malonic acid in the accompanying formulæ. a', b', c' represent points in the enzyme which specifically combine with the groups a, b, c of the substrate. Evidently, decarboxylation could occur at a' but not at b', or *vice versa*. The same conclusion follows if any three of the groups of the substrate specifically combine with the enzyme. If decarboxylation occurs only at b', then all the isotopic carbon in the carboxy group of serine will appear in the glycine. The case of the formation of ketoglutarate from citrate is exactly parallel.



l-Serine

Amino-malonic acid

This argument depends on two conditions: (*a*) that the sites a' and b' are catalytically different; (*b*) that three-point combination occurs between the symmetrical substrate and the enzyme; such combination is, of course, necessary wherever a single optical antipode is formed enzymatically from an inactive precursor. Since neither is unlikely, it follows that the asymmetrical occurrence of isotope in a product cannot be taken as conclusive evidence against its arising from a symmetrical precursor.

Cultivation of *Trypanosoma cruzi* in the Developing Chick Embryo

ALTHOUGH *Trypanosoma cruzi*, the causative agent of Chagas' disease in South America, has been successfully cultivated in the embryonic tissues of the chick, attempts at growing this parasite in the developing chick embryo have hitherto led to inconclusive results. Roubaud and Romana[1] inoculated *T. cruzi* into the chorio-allantoic membrane of chick embryos from (*a*) a rich culture; (*b*) drops of liquid excreta of *Rhodinus prolixus* containing metacyclic forms; and (*c*) citrated blood of an infected guinea pig containing numerous large and active trypanosomes. The results were negative, and no infection was observed, except that in one embryo inoculated with the citrated blood a single trypanosome was found to have persisted on the membrane a week after inoculation. Rodhain and van den Berghe[2] inoculated a dozen eggs with a strain of *T. cruzi* cultured in Novy–MacNeal–Nicolle medium. Three of the embryos became 'infected'; but attempts to effect a second passage in embryos did not succeed, and sections of the membrane of an 'infected' embryo did not show any trace of an invasion of the membrane or intracellular developmental stages. Rodhain and van den Berghe concluded that a true infection had not been established and that, probably, cellular invasion of the chick embryo does not occur, but that, as the parasite grows readily in tissue cultures of the chick embryo, the results need verification.

Recently I have succeeded in producing infection in chick embryos with both cultural and blood forms of *T. cruzi*.

The strain of *T. cruzi* was obtained from Dr. D. G. Davey, Imperial Chemical Industries, Manchester, on February 4, 1943, and since has been maintained in this Institute in mice. The inocula were composed of (*a*) equal parts of heart blood (drawn aseptically) from infected mice and sterile citrate-saline solution; and (*b*) a rich culture on Novy–MacNeal–Nicolle medium. The eggs were used after 10–14 days incubation, and the inoculations were made on to the chorio-allantoic membrane by the standard technique described by Beveridge and Burnet[3]. The eggs were opened from the third day onwards after inoculation, the membrane was fixed for sectioning, and heart blood from the embryo was examined for trypanosomes.

Twenty-four embryos were inoculated, twelve with culture and twelve with the citrated blood. Six were found dead on opening, and were discarded. All the others were infected and showed characteristic macroscopic lesions on the membrane which, on microscopic examination of the sections, are seen to be produced by the invasion of the membrane by the parasite and its active intracellular multiplication. All the stages of intracellular development characteristic of the parasite in the vertebrate host have been found in the membrane. The free extracellular trypanosomes appear in the blood of the embryo on the fifth day after inoculation. None of the inoculated embryos has so far survived to hatch out.

Macroscopically, the lesions appear as whitish opaque granulations scattered over the entire inoculated area of the membrane (Fig. 1). In some cases a tendency for the lesions to concentrate into groups was observed. The membrane as a rule is thickened and rigid, and the blood vessels tend to dilate. The lesions are evident on the third day after inoculation and become very numerous and highly specific on the fifth day.

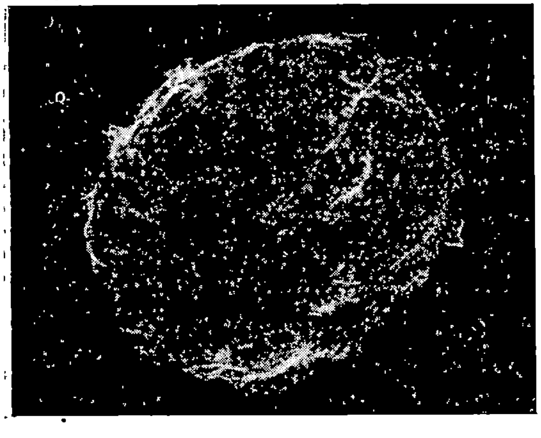

Fig. 1. Photograph (approximately one and a half times natural size) of chorio-allantoic membrane showing typical specific lesions produced by *T. cruzi* five days after inoculation with a culture in Novy–MacNeal–Nicolle medium

Sections of the infected membrane show numerous 'cysts' on the surface of the ectoderm or deeper down in the same layer. These 'cysts' enclose large numbers of leishmania stages of *T. cruzi*. Apparently the individual trypanosomes from the inoculum invade ectodermal cells and round up into leishmania stages which then undergo repeated divisions. The infected cell is ultimately reduced to a bag or membrane surrounding the parasites, and this gives rise to the characteristic 'cyst-like' appearance. The host cell is very much hypertrophied and its nucleus large and degenerate. The ectodermal cells around the invaded cell proliferate actively and the whole area gets considerably thickened, thus forming the characteristic lesion. It is usual to find several such groups of leishmania stages inside one lesion (Fig. 2). The crithidial forms have been observed in sections of membrane fixed five days after inoculation. The proliferation of the ectoderm cells is accompanied by cornification and necrosis. The mesoderm layer is unaffected, except for the presence of large numbers of eosinophil leucocytes and for slight œdema. Red blood cells and leucocytes are frequently seen below the ectoderm. The endoderm does not appear to be affected in any way.

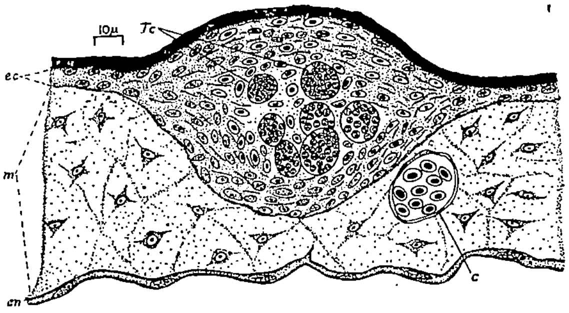

Fig. 2. Section of chorio-allantoic membrane showing a lesion containing leishmania stages of *T. cruzi* three days after inoculation with citrated blood of an infected mouse: *c*, capillary; *ec*, ectoderm; *en*, endoderm; *m*, mesoderm; *Tc*, Leishmania stages of *T. cruzi*

Thus, contrary to the results obtained by previous workers, it has been found that chick embryos, of 10–14 days incubation, may be infected readily with either cultural or blood forms of *T. cruzi*, and that characteristic lesions are developed in the chorio-allantoic membrane of the infected embryos. The cultivation of *T. cruzi* in chick embryos opens up a promising field for studies on the action of drugs on the intracellular stages of this trypanosome. Further experiments are in progress, and a fuller account of the intracellular development of *T. cruzi* and the histopathological changes in the host will be published elsewhere.

My thanks are due to Dr. P. Tate for supplying infected mouse blood for the above experiments.

Phosphorylation of Myosin by Adenosine Triphosphate

THE study of the interaction between actomyosin and adenosine triphosphate has hitherto given evidence of physical changes in the protein and of its enzymic activity. Very little was known, however, of chemical changes in the protein molecule accompanying the physical effects. Phosphorylation of the protein[1] and formation of an adenosine triphosphate-protein compound[2] have been suggested as alternative possibilities, but conclusive experimental evidence has not yet been presented.

* 2 × 10^{-6} mol./ml. adenosine triphosphate.

† 2 × 10^{-6} mol./ml. adenosine triphosphate + 1 × 10^{4} mol./ml. potassium chloride + 1 × 10^{-5} mol./ml. magnesium chloride.

Actomyosin and actin-free myosin threads contain appreciable amounts of adenine, ribose and phosphorus which cannot be removed by repeated washing, but are extractable after denaturation. In the protein-free extracts the phosphorus is present as orthophosphate (P_0), readily hydrolysable phosphate (P_7—P_0) and difficultly hydrolysable phosphate (P_T—P_7).

Treatment with adenosine triphosphate causes a considerable increase in adenine, ribose and the different phosphate fractions, not removable by repeated washing (see table). The ratio of readily hydrolysable phosphate and phosphate hydrolysable with difficulty to adenine corresponds roughly to the ratio calculated for adenosine diphosphate.

The uptake of adenine, ribose and phosphate can be observed only after the application of adenosine triphosphate. No uptake of either nucleotide or phosphate follows treatment of the protein with adenosine diphosphate, adenylic acid, orthophosphate or pyrophosphate. The effect of adenosine triphosphate is independent of the adenosine triphosphatase activity of the protein, as threads from preparations with high and low enzymic activity give the same results. Inosine triphosphate and inorganic triphosphate, which are both split by adenosine triphosphatase, produce neither an uptake of nucleotide nor of phosphate. Furthermore, an increase in temperature from 0° C. to 37° C. is accompanied by a much higher increase in enzymic activity than in nucleotide and phosphate uptake.

The orthophosphate found in the protein-free extract must originate from highly labile phosphate bound to the protein, that is, it is the expression of a phosphorylation of the protein. It can scarcely be present as orthophosphate before denaturation, because orthophosphate is quantitatively removed by the washing preceding denaturation.

While phosphorylation and nucleotide uptake are independent of the enzymic activity of the protein, a close correlation exists between chemical effects and constriction of volume. Both phenomena require the presence of adenosine triphosphate, which is highly specific for both reactions. In increasing concentrations adenosine triphosphate causes increasing phosphorylation and nucleotide uptake as well as increasing volume constriction. Addition of magnesium salts, which enhances the latter effect, also increases phosphorylation.

Adenosine triphosphate causes phosphate and nucleotide uptake both in threads of actomyosin and actin-free myosin, whereas the constriction of volume occurs only in the presence of actin. Hence, the chemical changes must be localized in the myosin moiety of the protein.

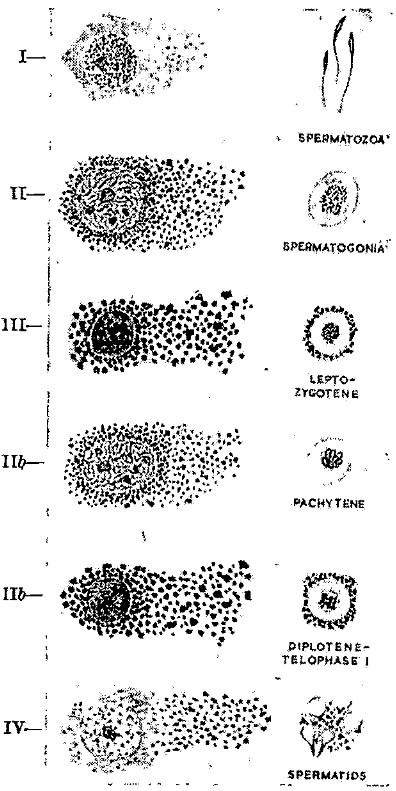
Ribonucleic Acid Supply and Phosphatase Distribution during the Spermatogenesis of *Asellus aquaticus*

STUDIES on the spermatogenesis of *Asellus aquaticus* L.[1] directed attention to the polyploid cells surrounding each testicular lobe. It has been found that these cells show cyclic variations of morphological characters both in nucleus and in cytoplasm which correspond to different phases of spermatocytic evolution. The latter is almost synchronous in each lobe, and a small bunch of spermatogonia remains in the basal portion of the lobe, to ensure the next spermatogenetic wave.

The nuclei of the surrounding cells are polyploid of the *Gerris* type[2], that is, with chromosomes



preserving their individuality. No large chromocentre is present. The cytoplasm may be more or less filled with basophil granules, which tested by Brachet's method (Unna–Pappenheim stain and control by pretreatment with ribonuclease) appear to be very rich in ribonucleic acid, perhaps entirely formed of this substance.

The variations may be summarized as follows. Stage I corresponds with fully formed spermatozoa. Nucleus large, chromatin of each chromosome much contracted. Cytoplasm devoid of granules. Stage II corresponds with spermatogonia. Nucleus larger, chromatin much more dispersed and chromosomes threadlike. Cytoplasm with a few granules, especially abundant around the nuclear membrane. A few granules are found excreted between the spermatogonia. The spermatogonial cytoplasm stains pink with pyronin. Stage III corresponds with spermatocytes in lepto-zygotene. Nucleus small, very contracted, chromatin more diffuse. Cytoplasm heavily charged with large granules of ribonucleic acid, which are excreted into the interstices between the spermatocytes. Spermatocyte cytoplasm stains a brilliant pink. Stage II *b*. At pachytene the follicular cells are again in stage II, and the germ cells appear to have exhausted their supply of ribonucleic acid in cytoplasm. Stage III *b*. At diplotene to telophase I, the follicular cells are again in stage III, while the cytoplasm of the germ cells stains red (especially so at metaphase I). Stage IV corresponds with telophase II to spermatids. Chromatin resumes the granular form (that is, contracted chromosomes). The cytoplasm is vacuolated and devoid of granules. Some of them are still present outside the cells and between the young spermatids, the majority of which have their tails oriented toward the clots of granules.

There are one or two nucleoli in every stage except stage II, in which three to six supplementary nucleoli appear. In every stage nucleoli stain faint pink, except in stage III, in which the main nucleoli stain deep red.

With Gomori's technique for phosphatases, using as substrate either sodium glycerophosphate β or polymerized desoxyribonucleic acid or ribonucleic acid, the following results have been obtained. (*a*) The monophosphatases and diphosphatases are present in the nuclei, both of follicular cells and germ cells; they are localized on chromatin and nucleoli (see below). They are probably absent from the cytoplasm and certainly from the granules. (*b*) Mono- and diphosphatases are present in the main nucleolus at every stage. In stage II they are present together in two or three of the supplementary nucleoli, while in the remainder only monophosphatases are present. Since it is probable that phosphatases are concerned with the metabolism of nucleic acids[3-5], we are inclined to think that the metabolism of ribonucleic acid occurs only at two points, namely, (i) the polyploid nucleus as the starting point, and (ii) the germ cell nucleus as the end point. Moreover, it appears that the highest charge in phosphatases corresponds to stage III, so that probably this is the phase with the greatest production of ribonucleic acid.

From the observations it follows that: (*a*) The follicular cells elaborate and secrete ribonucleic acid, which is supplied to the germ cells. (*b*) The nucleus takes part in the secretory activity of the cell and shows evident structural changes. (*c*) During a spermatogenetic cycle the polyploid cells undergo two waves of secretion, with two peaks corresponding respectively to lepto-zygotene and diplotene-telophase I. (*d*) Spermatocytes absorb and utilize ribonucleic acid, which is supplied in this way by the follicular cells.

The mechanism of feeding nucleic acids to the male germ cells of *Asellus* thus differs slightly from that found by Painter and Reindorp[6] in the oocytes of *Drosophila* and by Painter[7] in the anthers of *Rhœo.*

Electrical Resistance of Wires with Large Strains

SOME time ago, K. H. Swainger[1] directed attention to the remarkable linearity of the electrical resistance of 'Minalpha' wires with large strains, optically measured. As this observation has important consequences on strain measurements, it seemed worth while to examine wires of other materials for the effect. Preliminary experiments showed that for all materials tested the specific increase of the electrical resistance was approximately equal to twice the specific elongation of the wire, if well above the yield point. This result made it obvious that the change of the electrical resistance is mostly a geometrical property, and was not due to a change of the resistivity of the material.

Thus, with the two assumptions that the resistivity of the material and the volume of the wire remain unchanged at large strains, it is easy to see that the resistance R with its initial value R_0 is connected to the actual length L of a uniformly strained wire of initial length L_0, by the expression :

$$\frac{R}{R_0} = \left(\frac{L}{L_0}\right)^2;$$

which for small values of $\Delta L/L_0$ may be written

$$\frac{\Delta R}{R_0} = 2 \cdot \frac{\Delta L}{L_0}.$$

'Copel', a copper–nickel alloy from the Hoskins Manufacturing Company, Detroit, has shown the largest elongation, with the remarkable value of about 35 per cent, but we have in some cases found values as high as 60 per cent. As may be seen from Table 1, the two basic assumptions are excellently verified for this material.

Table 1. Static test on 'Copel' wire. $L_0 = 125$ mm.; diameter, 0·45 mm.

ΔL (mm.)	R (ohm)	R/R_0	$(L/L_0)^2$
0	0·376	1·000	1·000
6·25	0·414	1·101	1·102
12·50	0·455	1·210	1·210
18·75	0·497	1·322	1·322
25·00	0·542	1·442	1·440
31·25	0·588	1·564	1·562
37·50	0·635	1·689	1·690

Wires of other materials showed resistances a little less (0·5–1 per cent) than the calculated values, probably due to the elastic part of the strain.

As the electrical resistance is determined by the dimensions of the wire only, it seemed plausible that the rate of strain would not affect the resistance-strain relation, though it affects strongly the stress-strain curve.

In order to confirm this, the wire was rapidly stretched by releasing a spring, between which and the wire a plate provided with slits at 2-mm. intervals was inserted. The resistance-time curve was taken as an oscillogram, on which every 2 mm. of elongation were marked using a photocell guided by these slits. The results are shown in Table 2, where v denotes the velocity of the moving end of the wire.

Table 2. Dynamic test on 'Copel' wire. $L_0 = 101$ mm.; diameter, 0·45 mm.

v (m./s.)	ΔL (mm.)	R (ohm)	R/R_0	$(L/L_0)^2$
0	0	0·303	1·000	1·000
1·8	2·1	0·316	1·043	1·042
2·6	4·1	0·328	1·082	1·083
3·1	6·1	0·342	1·129	1·124
3·5	8·1	0·354	1·168	1·167
3·9	10·1	0·367	1·211	1·210
4·4	14·1	0·394	1·300	1·299
4·8	18·1	0·422	1·393	1·391
5·2	22·1	0·451	1·488	1·485
5·6	26·1	0·477	1·574	1·584
5·9	30·1	0·509	1·680	1·685
6·2	34·1	0·541	1·785	1·789

Similar results have been obtained with a 200-mm. wire. The differences between the two last columns lie within the errors of observation.

We have found it possible to use these plastic strain gauges with advantage to measure the extremely rapid increase of diameter of detonating shells and the like.

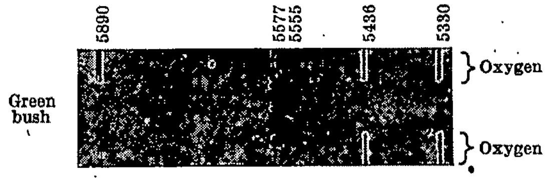
The Green Auroral Line as an Initiator of Phosphorescence in Condensed Systems

In 1924 one of us (L. V.)[1] detected a number of phosphorescent bands produced when solidified mixtures of nitrogen with inert gases (argon or neon) were exposed to the bombardment of cathode rays. One of these bands, called N_1, was situated in the region of the green auroral line. With diminishing nitrogen concentration the width of the line diminished and in pure neon it took the shape of a diffuse line with a wave-length 5577·4 A., which within the limit of error was identical with that[2] of the auroral line 5577·35. From this result, Vegard concluded that he was actually observing the green auroral line, which, however, under certain conditions took the form of a phosphorescent band, due to the action of Van der Waals' forces[3] between the molecules of the condensed system.

After McLennan and collaborators had shown that the green auroral line originated from transitions between the metastable ground-states $^1S_0$ and $^1D_2$ of the normal oxygen atoms, Vegard[4] expressed the view that the coincidence between the auroral line and the N_1-band observed in solidified inert gases and in their mixtures with nitrogen was not likely to be accidental, and that further studies of the phosphorescent band might show some relationships ; in other words, that the band was initiated by traces of oxygen, which act as nuclei of the phosphorescence. Now we have recently been able to study a most interesting luminescence effect which strongly supports this view.

In connexion with the production of inert gases undertaken by the Norwegian firm "Norsk Hydro-Elektrisk Kvaelstofaktieselskab", J. Nordhagen recently found that a sample of purified argon, when tested at atmospheric pressure by a Tesla transformer, showed a green bush of luminescence not previously found by similar tests of other samples. It was therefore of importance to find the origin of the phenomenon in order to make sure that it was not due to impurities of some sort. We were consulted on the matter and asked to undertake a spectral analysis of the luminescence.



The spectrograms showed that the green bush consists of a single green band dominated by a somewhat diffuse line with continuous light on both sides. The wave-length of the line was measured and found to be 5577. Thus within the limits of error, the wave-length is equal to that of the auroral line 5577·35 A. A spectrogram was also taken with a comparison spectrum obtained from an oxygen discharge tube which gave the green auroral line. As seen from the reproduced spectrogram, the line in the phosphorescent band from argon coincides exactly with the auroral line. The spectrograph had at this wave-length the fairly large dispersion of 50 A./mm. Towards longer wave-lengths the continuous light extends to 5585 ; and towards short wave-lengths to about 5400.

The reason for the different behaviour of the old and new samples was found to be that the latter contained less oxygen. When the oxygen concentration of the new sample was increased to that of the previous ones, the green phosphorescence disappeared. Thus the essential condition for the appearance of the phosphorescent band initiated by the green auroral line is that oxygen is present in extremely small concentrations. The green luminescence showed an afterglow, sometimes lasting for a few seconds.

In the experiments with the *solidified* gases, previously referred to, the solid layers unavoidably contained traces of oxygen, and it is therefore very likely that the green N_1-band, which in neon had the wave-length 5577·4, is a phosphorescence phenomenon initiated by the green auroral line. In solidified systems a red band N_3 (6320) was observed, which might be initiated by the red auroral O I-doublet (6300·3, 6364).

In the case of gaseous argon we have not yet observed a red band corresponding to the red O I-doublet.

Investigations into the nature of this phosphorescence phenomenon, detected by Mr. Nordhagen in gaseous argon containing traces of oxygen, will be continued.

Some New Ferromagnetic Manganese Alloys

The ferromagnetic beta phases in the systems copper–manganese–aluminium and copper–manganese–tin have been shown to have an ordered body-centred cubic structure, and the compositions of alloys showing maximum magnetizations correspond to atomic proportions[1,2] Cu_2MnAl and Cu_2MnSn. Valentiner has recently reported that ferromagnetic alloys exist in the system copper–manganese–indium. The highest intensity of magnetization is shown by the composition Cu_2MnIn, and the structure is analogous to that[3] of Cu_2MnAl and Cu_2MnSn.

The position of gallium in the periodic table relative to aluminium, indium and tin, and the similarity of the equilibrium diagrams of the binary systems copper–aluminium, copper–tin, copper–indium and copper–gallium suggest that a ferromagnetic beta phase might exist in the ternary system copper–manganese–gallium.

We have investigated three copper–manganese–gallium alloys having the following compositions (Table 1).

Table 1

Alloy designation	Weight per cent Cu	Mn	Ga
*G*1	49·5	21·6	28·9
*G*2	62·3	13·0	24·7
*G*3	57·8	16·0	26·2

Specimens of alloy *G*1 quenched from temperatures between 500° C. and 750° C. all showed a two-phase structure under the microscope, and were very feebly magnetic. The highest intensity of magnetization was shown by a specimen quenched from 650° C. This specimen had a saturation magnetization at room temperature of about 2½ per cent of that of nickel. This value was doubled on ageing the specimen at 100° C. for 110 hours. The composition of alloy *G*1 corresponds to atomic proportions $Cu_{1\cdot97}Mn_{1\cdot00}Ga_{1\cdot05}$.

Alloys *G*2 and *G*3 were quite strongly magnetic after being quenched from 750° C., and under the microscope had an acicular appearance like martensite. Alloy *G*3 had a saturation intensity of magnetization at room temperature about seven-tenths of that of nickel. Cooled slowly from 750° C., this alloy became non-magnetic, and microscopic examination showed that a transformation had taken place. Ageing of alloy *G*3 at 100° C. and 200° C., following quenching from 750° C., caused a reduction in saturation magnetization; but no transformation was apparent under the microscope.

Table 2. X-ray diffraction data for alloy *G*3 (quenched from 750° C.)

Radiation	Intensity	*d*	Radiation	Intensity	*d*
FeKα	ww	2·446	FeKβ	ww	1·328
β	ww	2·294	α	m	1·335
α	m	2·286	β	ww	1·292
β	ww	2·122	α	s	1·295
α	s	2·127	α	s	1·207
β	m	2·019	α	w	1·148
α	ss	2·018	α	m	1·135
α	m	1·968	α	ss	1·108
α	m	1·556	α	m	1·076
α	m	1·532	β	w	1·062
α	m	1·371	α	m	1·067
			α	w	1·011

X-ray diffraction photographs were taken at room temperature of powder specimens, quenched from 750° C., of alloys *G*2 and *G*3. Both patterns were of the same type, and the data for alloy *G*3 are listed in Table 2. A satisfactory interpretation of these data could not be made. The lines observed cannot be reconciled with those to be expected from the beta structure, ordered or unordered. Weibke states that the beta copper–gallium alloys resemble beta copper–aluminium alloys in that the structure of quenched alloys depends upon the cooling velocity[4]. The same behaviour was noted by Hume-Rothery and Raynor[5]. The martensitic structures observed in quenched alloys could possibly be derived from the beta phase, stable at high temperature, but not retained by quenching.

Preliminary experiments have shown that ferromagnetic phases exist in the binary systems manganese–germanium and manganese–indium, and in the ternary system copper–manganese–germanium. Investigation of these systems is being extended with the view of identifying the ferromagnetic carriers. It is also suggested that ferromagnetic phases might exist in the binary system manganese–gallium.

Addition of Maleic Anhydride to Anethole

In a communication bearing this title, and when referring to our papers[1] on the uncrystallizable compound (m.p. 311–312°) formed during the course of the reaction which takes place between anethole and maleic anhydride, Bruckner and Kovács[2] state that we have not recognized that this compound was a heteropolymer. In a series of other reports on the same subject published later, the heteropolymer character of the compound was established and, furthermore, its molecular weight was determined[3] with the help of the *cis*-hexahydro-*para*-aminobenzoic acid lactam[4]. The product which is obtained first under Bruckner's working conditions and our own, when refluxed with chloroform, yields two compounds, one of them soluble (m.p. 245° decomp.), with a molecular weight equal to 738 (theoretical for 3 : 3·735), and the other insoluble (m.p. 310° decomp.), with a molecular weight equal to 1,010 (theoretical for 4 : 4·980).

Bruckner and Kovács refer to the structure of the crystalline compound (m.p. 241°) formed by one mole of anethole and two moles of maleic anhydride, obtained by Bruckner in small quantities[5], and which he now obtains with a 60 per cent yield when a small amount of dimethylaniline is added.

We have found a crystalline compound (m.p. 232°) in this ratio of 1 : 2 with a yield of 30 per cent, when the condensation is carried out in the presence of hydroquinone, which acts as an inhibiting agent towards polymerization[3]; and, moreover, we have characterized crystalline products with the same molar ratio in the condensation of maleic anhydride with *o*-metoxypropenylbenzene (m.p. 241°)[6] and 1-4-metoxypropenylnaphthalene (m.p. 256–257°)[7].

Concerning the structure of the compound formed, Bruckner considers that, from the point of view of diene synthesis, anethole behaves as a conjugated tetraene which would react successively as shown by I and II. Though we do not deny this possibility, we have directed attention to the possibility that the reaction takes place in the form indicated in III and IV, where the second molecule of maleic anhydride would react, following a process of substitution addition already mentioned by Adler[8] as coincident with the diene synthesis.

The ultra-violet absorption spectra of these compounds are of the same type as that found for tetraline. When heated with selenium to 220°, characterization of the corresponding methyl-oxy-dicarboxylic acids, formed through loss of the second maleic anhydride molecule, is accomplished. With Bruckner's structure this may evidently take place due to the tendency of the nucleus to become aromatic; with our own, through elimination of the lateral chains, in this case of succinic acid, a process usually accompanying the hydrogenation reactions. On the other hand, in the case of 1-4-metoxypropenylnaphthalene it would be necessary to make allowance, following Bruckner, for the entrance of a second molecule as shown in V, and furthermore for the possibility of a new molecule adding itself to the conjugation in *A*; but we have found no compounds in the ratio of 1 : 3.

We are studying now the possibility of a reaction of substitution addition with the allylic isomers of these diene compounds which, taking place in these cases with transposition[9], gives rise to a conjugation capable of reacting, in the form of a diene synthesis, and producing compounds showing a structure which can be compared to that of those under consideration. The results and details of these investigations will be published elsewhere.

Interpretation of Data from Electrical Resistivity Geophysical Surveys

In connexion with the note by J. M. Hough on work by himself and Prof. L. S. Palmer of University College, Hull[1], I should like to direct attention to a method I described briefly in 1934, and which I have been practising since that date[2].

It will be noticed that I use the ratio ρ_a/ρ_1 for application to standard curves, of which I have sets in many forms. In all cases I obtain solutions by superposition of field curves on transparent paper, having long ago calculated sufficient values for complete sets of curves.

In the solution of multilayer problems I have used proportional compasses and thereby obtain four or five similar curves for superposition on standard curves, from which the 'scale', that is, the effective value of ρ_1, is obtained. I am grateful for the suggestion of using logarithmic plots, which are similar in shape and result merely in a shift of the axes according to 'scale'.

Finally, I would like to suggest to Prof. Palmer and Mr. Hough that a day in the field using my method will convince them of the advantages of my lay-out, in which a is fixed and α varied. A small handbook is now in the press giving details of the method and standard curves for the use of Survey officers.

Incidentally, there is a printer's error in the formula in my paper[2] at the foot of p. 276, owing to my not being able to check the proofs; it should read:

$$\frac{\rho_a}{\rho_1} = 1 + 2f(f+1)$$

$$\sum_{n=1}^{n=\infty} k^n \left[\frac{1}{(f^2 + 4\lambda^2 n^2)^{1/2}} - \frac{1}{((f+1)^2 + 4\lambda^2 n^2)^{1/2}}\right]$$

[2] *Mining Mag.* (Nov. 1934).

The comparison of field curves with sets of standard curves, as suggested by Mr. W. G. G. Cooper, is one method of interpreting results. This method requires a large number of standard curves even for the two-layer case, as there are two variables, namely, the depth of the surface layer and the ratio of the resistivities of the two layers. The number of standard curves is reduced to a single set when logarithmic curves are used, as suggested by Whitehead and Radley[1] and in my original letter[2]. Mr. Cooper agrees with me that for multi-layer curves the use of logarithmic curves is a definite advantage.

Mr. Cooper's method for field-work has obvious advantages over our method in needing a smaller operating team. When α is small, the potential difference between the potential electrodes is small, and this may cause the method to be insensitive for these readings. Although the usual electrode-layout is that due to Wenner, there are many other possibilities, and we hope to make an investigation into some of these in the near future. We expect that the most suitable electrode arrangement will depend upon the particular geological structure to be investigated.

Blinking

In recent discussions on blinking[1], it has been taken for granted that, in a physical experiment, an object cannot be kept under continuous observation. The difficulty, however, is easily overcome. It is easy to acquire the habit of blinking the eyes alternately and, provided the period is made slightly shorter than that associated with normal blinking, no discomfort results.

I have used this technique in the laboratory for more than twenty years, and have always assumed that it was generally known; but this, apparently, is not the case.

R. E. D. CLARK

St. John's College,
Cambridge.

[1] Lawson, R. W., *Nature*, **161**, 154 (1948); **162**, 531 (1948).

DR. CLARK'S interesting and novel method of avoiding the interruption of vision due to blinking assumes that blinking is suppressed when the subject 'winks' periodically with alternate eyes. After repeated trials, I doubt whether this assumption is justified. Moreover, few people are aware of their normal rate of blinking.

Almost the whole of the lid movement during blinking is performed by the upper lid, and the two lids meet roughly at the level of the base of the iris. The period of blackout during blinking is made up of two parts: the time taken by the upper lid to traverse in both directions the lower iris, and the time during which the lids are in contact. In general, the vision is 'mobile' during the whole of the blink, and for a short time afterwards (Lawson, *l.c.*). Both blackout and mobile vision become serious only at relatively high rates of blinking.

In 'winking', on the other hand, the lid movement is shared about equally by the upper and lower lids, and contact is established in general over the pupil. The period of blackout for each eye is consequently restricted to the time of contact of the lids, and is thus shorter than the blackout due to blinking. The vision of the winking eye is, however, mobile during the whole of the wink, owing to the development of a mobile diplopia caused apparently by refraction in the superficial corneal fluid as the lids approach each other. The existence of this diplopia in binocular vision during winking can readily be demonstrated by holding the wink, when two images are clearly visible. For myself it amounts to about 1° in the field of vision, the direction of displacement varying from subject to subject. On the other hand, the mobile vision due to eyeball rotation associated with blinking amounts to only $\frac{1}{2}$° in the field of vision (*l.c.*).

Thus, although the effect of blackout is largely eliminated by the process of 'winking' alternately in binocular vision, mobile vision is enhanced and becomes much more disturbing. The 'cure' seems to be worse than the 'disease', and I am not clear how it can be applied to observations through a 'monocular' microscope.

GEOLOGY AND MINERAL RESOURCES OF AFRICA

AT the eighteenth session of the International Geological Congress held in London during August last, the Association of African Geological Surveys held a series of four meetings at which recent advances in the geology of Africa were announced, and discussions of special interest took place. The meetings were of truly international character, and the great interest they aroused is clear from the large attendances and the very considerable number of papers that were presented. Indeed, in many cases only the briefest time could be given to the reading of the papers, but the discussions on the important problems dealt with were of special value. The meetings bore striking testimony to the results already obtained by international co-operation in the whole field of African geology, and in addition indicated the means by which this co-operation could be fruitfully extended.

An important part of the activities of the Association was the presentation of new sheets of the International Geological Map of Africa, together with the co-ordinated description of natural regions; there were also discussions on general and special problems of African geology, and personal contributions on territorial problems.

A full account of the proceedings of the Association has been given by M. F. Blondel, secretary of the Association and director of the Bureau d'Études géologiques et minières coloniales, Paris, in *Chronique des Mines Coloniales* (Numéro Spécial, No. 147, Sept. 15, 1948), a journal well known to African geologists, and it will appear also in due course in the *Comptes rendus* of the International Geological Congress.

Recent advances in the geology and mineral resources of the British African Colonies were summarized in a paper by the directorate of Colonial Geological Surveys, which was based on descriptions by the directors of the British African Geological Surveys, most of which were given in the form of lectures at the Imperial Institute during the preceding year. These lectures and associated papers are shortly to be issued by the Imperial Institute in one volume, which will provide a most useful summary of the present position regarding the geology and mineral resources of these important Colonies.

This was the second session of the Association, the first having been held at the previous session of the International Congress in Moscow in 1937. The formation of the Association arose largely from the need for discussing various problems connected with the preparation of the International Geological Map of Africa; it was found, too, that there were many other problems of an international character that could usefully be discussed at periodical meetings, and the Association was accordingly formed to meet at the same time as the International Geological Congress. The next meeting of the Congress at Algiers in 1952 will be of special interest to all interested in African geology.

At the first meeting of the present session of the Association, Sir Edward Bailey was elected honorary president, Dr. F. Dixey president, and M. Blondel was re-elected secretary; Dr. Dixey then took the chair. All the African Geological Surveys were represented, and during the meetings fifty papers were presented with a view to inclusion in the *Comptes rendus* of the International Geological Congress, and there were also 109 contributions to the discussions.

M. Blondel reported on the work of the Commission of the International Geological Map of Africa. The Commission, which was formed at the International Geological Congress in Brussels in 1922, had as its object the preparation of a geological map of Africa on the scale of 1/5,000,000; M. A. Lacroix was elected president, and M. de Margerie secretary-general. For various reasons progress was at first slow, and in 1934 the task of preparation was taken over by the Bureau d'Études géologiques et minières coloniales, Paris, of which the director, M. Blondel, became the deputy secretary-general of the Commission. Owing to the magnitude of the task it was soon apparent that it would have to be carried out by an international body, and the Association of African Geological Surveys was formed very largely with the object of assisting the work of the Commission. It is none the less important not to overlook the fact that the immense task of compilation, drafting and publication has been performed at the Bureau d'Études géologiques et minières coloniales by M. Blondel and his staff; and the progress made with the map since 1937, in spite of the devastation of the intervening war years, reflects the highest possible credit on these collaborators, to whom all interested in the geology of Africa owe a great debt of gratitude.

In presenting the report of the Commission to the Association, M. Blondel referred to the death of M. A. Lacroix, who had been president of the Commission since its inception. M. de Margerie, who had greatly facilitated the work in its earlier stages, was elected president in his place, Sir Edward Bailey and Prof. Fourmarier were elected vice-presidents, and M. Blondel secretary-general; and it was agreed that the Commission should comprise the heads of the various African Geological Surveys, and certain eminent geologists with special knowledge of Africa.

M. Blondel showed that, of the nine sheets into which the map was divided, the first (No. 1, North-West) was published in May 1936, and presented to the Congress in Moscow; but owing to the loss of the stock of prints during the War, a reprint was made in 1946. Sheet No. 2 (Centre, North) was published in 1948, and No. 3 (North-East) in 1947; No. 4 (West) was presented in proof to the Congress in London; No. 5 (Centre) and No. 9 (South-East) were presented in manuscript form for discussion; and No. 7 (South-West) is reserved for the legend. There remain only No. 8 (South Africa) and No. 6 (East Africa), which are in active preparation, and there is good prospect that the work of the Commission will be wholly completed by the next Congress.

This great work has been financed very largely by France and the French African territories, and by Belgium and the Belgian Congo; Uganda, Southern Rhodesia and Egypt have also assisted. Considerable additional funds are urgently required for the completion of the work. Too large a share has clearly fallen on some countries and too little on others, and it is of the greatest importance that the British Colonies, among others, who stand to benefit so largely by this work, should in the future take a far greater share in the financial burden than they have in the past.

Following the submission of M. Blondel's report, Dr. N. R. Junner proposed that a tectonic and mineralogical map of Africa should be prepared, and M. Blondel, on being asked, generously undertook this additional task, which should fulfil a want long felt by many African geologists.

Prior to the meeting, the Association had invited the various geological services in Africa to prepare descriptions of the regions for which they were responsible, and in almost all cases this invitation was accepted. During the meeting brief summaries of these contributions were given, covering the following extensive territories: French Morocco, Sahara, Libya, Egypt, French West Africa, Portuguese Guinea, the British Colonies, French Equatorial Africa, Western Belgian Congo, the Katanga, Angola, Northern and Southern Rhodesia, the Union of South Africa and South-West Africa, Madagascar. These papers present an excellent review of African geology in 1948, and it is hoped that they will all appear in due course in the *Comptes rendus* of the Congress.

A geological bibliography of Central Africa, with additions to 1944, recently published by Belgium and the Belgian Congo, was presented to the Association.

The Association had proposed for discussion a number of general subjects, most of which concerned the correlation of the older formations for the purposes of the International Map. A discussion on the Pre-Cambrian formations was opened by Prof. A. Holmes, who, on the basis of recent researches on the age determination of rocks by radioactive methods, and of the disposition of the different orogenic zones, suggested a number of correlations, which in some cases were at variance with those generally accepted. These views stimulated a most interesting discussion, in which many members of the Association took part.

There followed a discussion on the correlation of the Karagwe-Ankolean, Kavirondian, and Nyanzian formations of East and Central Africa, which again elicited much interesting information from many speakers. It was finally agreed that on the International Map these three formations should be shown by the same colour, but with different symbols. The correlation of the Akwapimian, Birrimian and Buem formations was vigorously discussed by West African geologists, and it was finally agreed that the legend should show the upward succession long adopted by the Gold Coast Geological Survey, namely, Birrimian, Tarkwaian, Akwapimian, but with a note that certain French geologists would place the Akwapimian much lower. The Buem was to be shown as Upper Pre-Cambrian, but with the reservation that it might be Cambrian.

Following a discussion on the age and correlation of the Upper Kundulungu and the Waterberg-Matsap, it was agreed that, on the map, these formations should be represented by one colour, and that in the legend the age should be left open, with the observation that the ages suggested by various geologists ranged from pre-Silurian to Devonian and even Carboniferous.

The value of African tillites for correlation purposes was discussed, as was also the importance of *Stromatolites* and comparable organisms in determining the age and relations of the older formations. It was at length agreed that owing to the lack of knowledge of the structure of these algal forms, they should be the subject of study by specialists; and on the motion of M. A. Jamotte, it was resolved that the International Palæontological Union should be invited to undertake a special study of them.

An extra meeting was devoted wholly to the problem of rift valleys, and following papers by Prof. R. M. Shackleton, Dr. R. B. McConnell and Mr. A. M. Quennell, a valuable and interesting discussion took place, in which many members participated.

A long discussion was devoted to the terminology of the African Pleistocene, and it was finally agreed to recommend the adoption of the resolution on this question by the African Pre-History Conference held at Nairobi in January 1947. A resolution was also passed recommending the formation of a sub-commission to study the distribution and correlation of the Kalahari Sands.

The question of the distribution, ages and origin of the African carbonatites also gave rise to a useful discussion.

Finally, during the last meeting of the Association, thirty-three personal contributions on the geology of the various territories of Northern, Central, Eastern and Southern Africa were noted, and certain of them briefly discussed.

It may be of interest to add that at a Specialist Geological Conference arranged in September by the British Commonwealth Scientific Organisation, in consequence of the presence in London of the delegates to the International Geological Congress, a discussion took place on the question of the formation of regional bureaux for the study of long-term fundamental research on African geological problems on a regional as distinct from a territorial basis.

This session of the Association of African Geological Surveys not only enabled many old personal contacts among African geologists to be renewed, but also led to many new ones; and the papers and discussions were of great interest and value not only because of the new observations revealed by them, but also on account of the stimulus they gave to international co-operation in the realms of geology and to a regional approach to many fundamental problems.

The Association recorded its appreciation of the invaluable services of its secretary, M. Blondel, not only in the successful organisation of the session, but also in co-ordinating the activities of the Association during the interval between the sessions of the Congress.

POWER SUPPLY AND THE ELECTRICAL ENGINEER

THE title "Means and Ends" given to the presidential address of Mr. T. J. N. Haldane to the Institution of Electrical Engineers on October 7 expressed at once the twofold character and the unity of his subject. An eloquent reaffirmation of the faith of the engineer in the ultimate value of his calling was made by Mr. Haldane in the second part of an address which in the factual sphere concerned itself with the position of electricity power supply in Great Britain and Western Europe.

Pointing out that as early as the beginning of the seventeenth century Francis Bacon had indicated that man's mental and material progress are inseparably linked with one another, Mr. Haldane said, "At present it is all too painfully obvious that for most of the world we are very far from having achieved even that modest level of material prosperity such as would provide reasonable conditions for widespread spiritual development, which must, I believe, be regarded as our ultimate objective. So there remains a vast task for the scientist and engineer, whose work should receive whole-hearted approval, provided the raising of standards of life is regarded as a means rather than an end in itself." It was against this philosophic background that Mr. Haldane reviewed the position of electricity supply in Great Britain and in Western Europe.

Referring first to the nationalization of this industry in Britain, and remarking that we might well be proud of the way in which the change to public ownership had been accepted, Mr. Haldane expressed satisfaction at the new British Electricity Authority's keen awareness of the special problems resulting from the unification of this great undertaking. The twenty years of successful operation of the Central Electricity Board engendered confidence in the future of the new Authority.

Mr. Haldane first gave a brief review of the broad economic position, in which he referred to the importance to the electrical export trade of co-operation of the British Electricity Authority with manufacturers so as to ensure that plant developed for home use should also be suitable and competitive for export, and he also mentioned the not inconsiderable part played by the independent consulting engineer in fostering British trade abroad. He then gave detailed consideration to power resources, drawing a clear distinction between the requirements for power and requirements for energy. Mr. Haldane commented on the important contribution which could be made by water-power schemes towards the meeting of peak loads. Any given water-power scheme will be limited to a certain average annual output of kilowatt-hours; but it is possible to install a large amount of plant and make a correspondingly large contribution to the peak-load problem at the expense of a reduced annual load factor. One of the existing hydro-electric schemes, the Galloway development, was designed for an annual load factor of about 20 per cent; and for the new Sloy station on Loch Lomond the designed load factor was only 10 per cent. Tidal schemes and large-scale wind-generation, because of the intermittent character of their supplies, could make little contribution towards meeting peak loads but could add appreciably to the total output of energy. "Intermediate between the two extremes of pure kilowatts and pure kilowatt-hours," he said, "comes the gas-turbine, burning oil, whose importance is mainly as regards kilowatts, with a contribution to kilowatt-hours limited by economic considerations. Gas-turbines permit the cheap provision of kilowatts, but, until coal can be used in place of oil, cannot be justified for load factors above about 10 per cent or 15 per cent. No doubt, nuclear fission, if and when used for power production, will also have special circumstances attached to its use, such as, perhaps, development only on a large scale in remote regions at a very high load factor. Our main source of both kilowatts and kilowatt-hours must, however, continue to be coal, whose use we can hope to improve by a further increase in operational economy and by limiting, where possible, transport of this fuel particularly by rail." Referring further to the gas-turbine, Mr. Haldane stated that several large gas-turbine sets of the order of 15,000-kW. capacity were at present under construction for use as peak-load plant. It might seem surprising that active consideration was being given to the possible large-scale use of wind power. "The renewed interest in the subject is due mainly to three factors: the existence of extensive grid systems into which intermittent supplies of energy, wherever produced, can be fed; the increased knowledge of aerodynamics; and the shortage of coal." The western shores of the British Isles are well suited to the large-scale development of wind power, and this source of energy deserves more attention than it has received in the past.

Referring to the siting of generating stations, Mr. Haldane said that there were, broadly speaking, three choices: at the load centre, at or near the pithead, or on an estuary site to which coal could be delivered by sea. Estuary sites far removed from the load centre were unlikely to compare favourably with generation at or near the pithead. An economic comparison relating to the London area showed that, once all the available estuary sites had been used, it would be advantageous to place the bulk of future generating stations near the coalfields, with high-voltage transmission to the load centre. Peak-load plant at the load centre might well consist largely of gas-turbines.

Second only in importance to the actual generation of the required amount of electric power came the provision of adequate transmission and interconnexion facilities. This function had been served in Great Britain up to the present by the 132-kV. grid; but consideration had been given to the desirability of providing an additional national busbar operating at a higher voltage. We were about to experiment with the use of 275 kV., which was regarded as adequate for the distances over which we had to transmit and was, incidentally, considered to be the highest voltage for which underground cables could be built at the present time. The highest voltage A.C. system in Europe was at present under construction in Sweden, where a large block of power would be transmitted a distance of about 600 miles at 380 kV. "It may well be desirable," said Mr. Haldane, "to proceed as soon as possible with the construction of such a very high voltage system superimposed on the existing 132-kV. grid."

Turning to the power problems of Western Europe, which are even more acute than those of Great Britain, Mr. Haldane showed on a map the distribution of energy resources. It had long been hoped, he said, that some day all the Western European countries would be interconnected so as to make better use of the available resources. "Technically it should be possible to have high capacity interconnexion extending eventually from Scandinavia in the north to France in the south, with further interconnexion to Austria, Switzerland and Italy. Economically it seems likely that this would be highly beneficial. In fact, few measures could be expected to be more beneficial to European economic life than such integration of power resources, meeting as it would one of the most urgent of Europe's problems and helping towards unification." In this connexion, the question arose of the desirability of a connexion between the British system and that of the Continent. Technically, an interconnecting link between, say, London and Paris by high-voltage cable across the Channel appeared practicable. The question was whether the expenditure would be justified by saving in plant and interchange of energy.

The second part of Mr. Haldane's address was concerned with the philosophical implications of the activities of the engineer and the reaction of present-day conditions on his outlook. "As engineers concerned with applied science," said Mr. Haldane, "we occupy a position intermediate between that of pure science and that of the branches of knowledge concerned with human affairs. We are very definitely concerned both with the advancement of scientific knowledge and with the problem of how this knowledge can best be applied to meet human needs. The latter function makes it particularly important that the general educational background of engineering training should be as wide as possible and should not exclude those branches of knowledge generally known as the humanities.

"The present difficulties due to the huge content of knowledge and consequent tendency towards excessive specialization have led to the disappearance at an early stage in education of any general study of religion or philosophy, so that at the age when young people are becoming able to think on such subjects the great majority proceed to concentrate on mastering the means of life and remain indifferent to, and almost oblivious of, its ends.

"Future generations may well be amazed at our acceptance of such a state of affairs, the existence of which I feel to be one of the strongest arguments in favour of the higher education of engineers being centred in the universities rather than in mono-technic colleges. Although even in the best of our universities there may be too much concentration on means and too little thought about ends, the engineering undergraduate does at least get and give the immense advantage of mixing with those who are studying totally different branches of knowledge. The whole atmosphere of a university engineering education can be influenced by contacts with the other faculties, including the humanities, and consequently study can be on a much broader basis than is possible in colleges or institutions dealing with one subject or group of subjects."

In summing up, Mr. Haldane remarked, "In providing the conditions in which the things of the spirit can come to full fruition we undertake a vital as well as a noble task in which we can have the utmost pride. But let us fully understand the nature of our task, and let us spend more time than we now do in considering the ends to which our work is directed."

MODERN DEVELOPMENTS IN FORESTRY

IN *Forestry Abstracts* (Commonwealth Forestry Bureau, vol. 10, No. 1 Abstracts (1)—(849), September 1948, Commonwealth Forestry Bureau, Oxford), Mr. J. J. MacGregor, of the Imperial Forestry Institute, Oxford, has an interesting paper on "Some Improved Techniques in Nurseries and on Planting Sites". There are many influences, he says, compelling foresters all over the world to revise time-worn practices. These influences are part of the general economic environment in which rising wages and relative shortages of labour are, perhaps, most significant. They have directly stimulated the search for more economic methods, machines and techniques. In a general way, current and recent developments have proceeded along the two main lines of 'rationalization' and the application of new techniques to specific operations. The latter, which includes the adoption of mechanization, improved processes with new tools and new treatments, forms the basis of the article.

In using the term 'rationalization' the author means it to be applied to the administration of staff, the training of subordinate workers, housing and amenities, the execution and close inspection of all work, and the provision of tools; on this last point of tools one might add that, until recently in ordinary forest work, they were few, simple and no different from those in existence during what may be called the pre-mechanized times. In the modern study of these methods Sweden has given the lead and has been in the position, during the past ten years, when so many were otherwise engaged, to make considerable progress; and mention must be made of Swedish reorganisation of piece-work rates, which require to be both flexible and easily understood. Both in North America and in Germany forestry experts have been making similar studies. One form of 'rationalization' has been the suggested centralization of forest nurseries, since it is held, and rightly so, that the efficient raising of large stocks requires highly skilled and experienced supervision. Whether, however, the small nursery on the private estate should be regarded as obsolete is a matter which is open to considerable argument. The big battalions are by no means the safest in a matter of this kind, for many reasons.

On the side of technical mechanical developments, North America takes the lead. In agriculture, the application of labour-saving devices has gone a long way, and a few have been adapted for forestry purposes. But it is felt that special investigations, which are indeed being carried out by those conversant with forest nursery and other wider forestry problems, will have a greater chance of giving the forester new mechanical implements suitable to his particular type of work. The article also deals with the transfer of planting stock (storage and packing), preparation of sites, stump removal, plough and cultivators (the Forestry Commission has had a considerable success based on experiments with heavy ploughs), sowing and planting, planting methods and machines.

LABORATORY GLASSWARE PRODUCTION

THE expression 'E-MIL' may not be quite so well known as some others which have become quite commonplace; but it is likely to become a mark of quality standard in future. Messrs. H. J. Elliott, Ltd., Treforest Trading Estate, Nr. Pontypridd, Glam., whose trade mark it is, already enjoy a reputation for high-quality glassware for quantitative work; but they laudably seek to enhance that reputation by aiming at still higher standards and by offering unconditional guarantees concerning their products, as well as improvements in the character and packaging of the articles.

In the first place, their volumetric glassware will be designated 'E-Mil Green Line' in the case of that which complies with National Physical Laboratory grade *A* specifications, and 'E-Mil Gold Line' for that of the grade *B* standard, the graduations of these varieties being filled respectively with insoluble green and yellow enamels. The pigments appear to be somewhat fluorescent, for they are easily visible in poor lighting, even with coloured solutions. Furthermore, the markings, which are fused into the glass, seem to be irremovable except by such chemicals as those which corrode the glass itself.

Stoppers in graduated flasks and cylinders have always tended to be troublesome owing to a propensity for 'seizing'. The new 'E-MIL' stopper is a valuable accessory. Accurately moulded from an almost inert plastic, it provides a gas-tight and liquid-tight closure to an orifice of British Standards Institution specification taper (although it is not of B.S.I. specification dimensions), but does not bind or seize up irremovably. It is understood that patent protection is being sought for this attractive article.

Nor is this all, for the firm has introduced another innovation. It feels that the old style of crating a number of items amid masses of wood-wool, straw, sawdust and the like is not good enough for precision equipment; the packing material might be dusty and soil the articles, even if paper wrappings are used in addition, and by no means does it ensure safe transport unless an expert is employed to pack and another to unpack. Even with this system, overhead costs can easily be inflated by 'on-the-floor' losses in transferring the goods to storage bins, then to shelves and counters and finally with, or sometimes without, further packing, to the possession of the ultimate user. The firm feels that it can reduce these losses by sealing each article into its own specially fitting carton, which will be unreturnable and will doubtless be retained by many a technician as it provides a convenient pigeon-hole for the safe storage of the article in his locker. It is obvious that the extra expenses of this carton packing will be offset by dispensing with crates, etc., and with the trouble of their recovery as returned empties, not forgetting the overhead expenses and office work associated with the latter.

This programme could not be so courageously planned by the management had it not the wholehearted loyalty of its employees, to whom it gives very strong incentives to produce not only quantity but also quality in whatever they are making. The result is not a mere 'master and man' condition but the development of what may be described as a happy family, some members of which are miners who can no longer follow their former employment because of the dreaded silicosis, some are ex-Service men whose injuries limit their capabilities in the way of earning a living, and others are women and young people with a flair for delicate manipulation. It is good to see them working with a will, and everywhere there is evidence—sometimes resonant—of happy and contented folk.

R. SUTCLIFFE

EDUCATION IN HAITI

THE U.S. Office of Education has undertaken the preparation of a series of basic studies in education in a number of Central and South American countries. This series of studies is part of a programme to promote understanding of educational conditions in the American countries and to encourage co-operation in the field of inter-American education. The project, part of a government-wide programme of cultural co-operation under the auspices of the U.S. Department of State, was begun in the autumn of 1943. It involves travel by Office of Education specialists in the various countries in order to gather information at first hand on their educational systems and to prepare reports for publication.

"Education in Haiti" (Washington, D.C.: Gov. Printing Office. 25 cents) is based on data collected by Prof. Mercer Cook during a twenty-two months stay in which, as supervisor of an English-teaching project which was initially sponsored by the U.S. Office of Education, he was able to make use of authoritative sources of information.

The total area of the Republic of Haiti is about 10,700 square miles, more than two-thirds of which is covered by highlands. This complicates the construction of roads and renders many villages practically inaccessible to commerce and to education. The high rate of illiteracy—estimated at about 92 per cent by some observers—should thus be attributed in some part to topography. No scientific attempt has ever been made to count the total number of Haitians, but an estimate made in 1937 puts the total population at about three millions. Of these, nine-tenths live in rural areas and, as in other Latin-American countries, the fundamental educational problem is that of the rural school. Already, in the words of a contemporary Haitian novelist, erosion has "bled the earth to the bone", and the problem of this agricultural country is to try to intensify its agricultural effort by educating the peasant in modern methods of cultivation and soil conservation. Until this problem of rural education is satisfactorily solved, Haiti seems destined to remain a desperately poor country. The converse is equally true. Progress has been made in recent years; but the deplorable facts remain that four out of five peasant children never attend school; that teachers' salaries are inadequate; that many school buildings are hopelessly unsatisfactory; that equipment and textbooks are often unobtainable; that malaria, yaws, syphilis, tuberculosis and hookworm have undermined the health of the Haitian; that, as one Haitian physician states, "the diet of the Haitian peasant has not changed since slavery days"; and that education has been tied up too closely with politics.

The language problem is also a considerable source of difficulty to Haitian educationists. The official language of the republic is French, while "not one peasant out of a 100 can even guess what is being said in that language"; all Haitians understand Creole and most of them speak it. From Prof. Cook's observations it is apparent that poverty, ill-health, politics and linguistics are the basic ills that beset the Haitian school teacher, and the greatest of these is poverty. "On less than the average income of a first-class American university, the Haitians must provide and maintain elementary, secondary, professional, rural and vocational schools for a population of approximately three millions."

Despite these and other obstacles, however, the Haitians, through their own efforts and with some aid from foreigners, principally French and North American, have, during the last twenty years, progressed along the road to enlightenment. Their schools are no longer entirely literary or classical, teachers are better trained and somewhat better paid; printed regulations are less frequently disregarded. Yet, as Prof. Cook has shown, much remains to be done, and his report will prove invaluable in concentrating attention on the state of education in Haiti.

T. H. HAWKINS

FORTHCOMING EVENT

Monday, December 20

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 8.15 p.m.—Prof. E. G. R. Taylor and Prof. W. M. Smart, F.R.S.: "The Navigator's Story".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

BIOCHEMIST (non-medical)—The Director of the Pathological Laboratory, General Hospital, Middlesbrough (December 25).

PRINCIPAL SCIENTIFIC OFFICER (with a First or Second Class Honours Degree in Mathematics or an equivalent qualification, and ability to apply mathematics to tidal movements, etc.) in the Royal Naval Scientific Service—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2336 (December 30).

PRINCIPAL SCIENTIFIC OFFICERS in the Headquarters Office in London of the Department of Scientific and Industrial Research—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2335 (December 30).

HORTICULTURAL OFFICER in Grade II of the National Agricultural Advisory Service—The Secretary, Ministry of Agriculture and Fisheries, 1–4 Cambridge Terrace, London, N.W.1, endorsed N.A.A.S. (December 31).

SENIOR RESEARCH OFFICER in the Organic Chemistry Section of the National Chemical Research Laboratory, Pretoria—The South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2 (December 31).

PHYSICISTS and MATHEMATICIANS (for unestablished posts in the Experimental Officer class) in Ministry of Supply research and development establishments in Southern England and South Midlands, for duties concerned with aerodynamics, armaments, ballistics, crystallography, fuels, heat, jet propulsion, radio and radar, and X-rays—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.398/48A (December 31).

SENIOR SCIENTIFIC OFFICER (Ref. A.403/48A) to lead a group of physicists and engineers studying effect of tropical conditions on Service materials and equipment, and a SCIENTIFIC OFFICER (Ref. F.429/48A) to work in analytical or biochemical investigations into deterioration of equipment under tropical conditions, at the Tropical Testing Establishment, Nigeria—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting appropriate Ref. No. (January 3).

DEMONSTRATOR IN THE DEPARTMENT OF BOTANY—The Secretary, Bedford College for Women, Regent's Park, London, N.W.1 (January 8).

READERSHIP IN DEMOGRAPHY at the London School of Economics and Political Science—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 20).

POSTGRADUATE STUDENTSHIPS in preparation for research into stored products entomology in the Colonial Empire—The Under-Secretary of State, Colonial Office, Research Department, Sanctuary Buildings, Great Smith Street, London, S.W.1 (April 30).

CHEMISTS IN THE JOINT DEPARTMENT OF CHEMISTRY, Federation of Malaya—The Director of Recruitment, Colonial Service, 2 Sanctuary Buildings, Great Smith Street, London, S.W.1.

RESEARCH ASSISTANT in the field of Organic Chemistry—The Secretary, King's College of Household and Social Science, Campden Hill Road, London, W.8.

LECTURER IN THE DEPARTMENT OF CHEMISTRY—The Principal, Borough Polytechnic, Borough Road, London, S.E.1.

SENIOR LECTURER IN THE DEPARTMENT OF ELECTRICAL ENGINEERING—The Secretary, Royal Technical College, Glasgow.

PHYSICAL CHEMISTS as Scientific Officers at a Ministry of Supply research and development establishment near London for duties in (*a*) high temperature refractories, (*b*) crystallography and practical microscopy, (*c*) spectrography and (*d*) plant development—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.1025/48A.

CHEMICAL ENGINEER IN THE DIVISION OF ATOMIC ENERGY (Production), Risley, to assist in the design and operation of a prototype plant with a view to helping in the design and construction of a large production plant—The Staff Section, Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs.

ASSISTANT EDITOR of *Science Abstracts*—The Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2.

REPORTS and other PUBLICATIONS

ACADEMIC AND PROFESSIONAL INCENTIVES

IN its report on "University Finance in Great Britain", dated July 1943, the British Association Committee on Post-War University Education recorded the view that the question of university salaries was the essence of the situation and should be given priority over almost everything else. The salaries of university staffs of all grades were, in the opinion of that Committee, hopelessly inadequate in competition with the world outside, and in the lower ranges, in some universities, inadequate to afford a reasonable standard of life under prevailing social conditions. In the older universities, the salaries of the non-professorial staff were considered not inadequate in the lower ranks, except for the few who devote themselves almost wholly to research. At the provincial universities, however, the average salary of the non-professorial staff was not more than £450–475 a year, as against £600–1,000 for Cambridge (omitting demonstrators and faculty assistant lecturers).

The British Association Committee asserted bluntly that we can expect neither to attract to the university staffs the pick of their graduates nor to have a satisfactory standard of performance on such salaries ; and it recommended an adequate number of senior lectureships and readerships carrying salaries of £700–1,000 a year. Beyond this, however, it was of the firm opinion that in the existing organisation of our society, all whole-time professors in all British universities should receive at least £1,500 a year at 1938 values. "The reputation of our universities," it was urged, "depends more on the quality of their professors than on any other single factor. For the sake of university teaching and research we should make it more easy to retain our very best men, and to attract outstanding men back from the outside world when they are still at the height of their powers."

Somewhat similar proposals were advanced by the Association of University Teachers in a report on "University Developments, 1944", adopted by the Council of the Association in December 1943, namely, a basic salary of £1,500 for professors, and salaries in the range £800–1,100 for senior lecturers and readers. These proposals were afterwards criticized by Bruce Truscot in "Redbrick and these Vital Days", who suggested that the basic salary of £1,500 for a professor was too low though not necessarily at the beginning, and that the British Association Committee's own recommendation implies a basic figure of £1,800. The general level of lecturers' salaries proposed by the Association, however, he regarded as too high ; and he urged that the principle of a salary scale for the professor is of vital importance and one which will be of real service in dealing with the difficulty that in certain subjects such as medicine, and possibly engineering, it may be necessary to pay considerably higher salaries in view of outside competition.

It is true that outside competition should not be the sole factor to be considered in determining professorial salaries; but it is from this point of view that some recent observations of Dr. C. E. Raven in addressing the Senate of the University of Cambridge, on resigning the office of vice-chancellor on October 1, have received publicity which has somewhat distorted them. Dr. Raven recalled that, when putting forward proposals for the stipends of its professors, the University was warned by the University Grants Committee that £1,450 was the maximum professorial salary which the Treasury would recognize. Dr. Raven said that it seemed plain that if the maximum income in academic life was so seriously below that obtainable not only in medicine and at the Bar, but also in the Civil Service and indeed almost all other professions, the universities could scarcely expect to induce men of the highest abilities to stay with them.

This, however, was not all. If professors were limited to such a rate, and there was to be any ladder of promotion, junior teaching officers could be given scarcely a living wage—certainly not a wage on which to marry and bring up a family. Dr. Raven referred particularly to the position of men who, after six or more years in national service, had gained fellowships or been elected to junior teaching posts, and who at the age of thirty were receiving salaries little different from those offered in 1939 to men of twenty-three. In view of the cost of living, it seemed inevitable that unless the university could improve its scales of pay, it would lose an increasing number of men.

That view, of course, ignores the other incentives which induce men and women to take up an academic life; but such incentives can scarcely operate if the salaries offered in the early years of academic life do not enable men and women to sustain modest standards of living such as those laid down by the Association of University Teachers in the memorandum issued before the War, which presented reasoned arguments for a minimum stipend of £500 for a married teaching officer to do his whole duty by a university and its students. The disparity between such academic salaries and those offered in industry is considerable and may well lead to untoward distribution of man-power if uncorrected. Dr. Raven, indeed, directs attention to one specific example of disparity which was obviously in the mind of the British Association Committee when its report was written; the findings of the Spens Report on the Remuneration of Consultants and Specialists, to which Dr. Raven refers, accentuate this disparity. As Dr. Raven suggests, it is on the face of it absurd that whereas the stipends of the majority of Cambridge professors do not rise above £1,550, a specialist appointed to the staff of a hospital is to be guaranteed a salary rising to £2,500 at the 1939 value of money. If the salaries of university teachers of medicine are raised to the figures specified in the Spens Report, the resulting anomalies in the scientific departments of a university will be intolerable as well as absurd.

The universities are clearly facing something of a dilemma, even if the terms may not be precisely as Dr. Raven suggests. The disparity between the pay of chemists in industry and in the universities is well known, and the professorial limit of £1,450 is a good deal less than a man of the highest ability could expect to earn, even if more laboriously or precariously, in the Civil Service or at the Bar, quite apart from industry or medicine. It has been made abundantly clear in discussions on scientific man-power and on scientific and industrial research during the last decade that any policy which denuded any one sector of national life, whether the universities, the Government service or industry, of its proper proportion of the new talent leaving the universities, would have untoward repercussions on the well-being of the nation as a whole.

The problem or dilemma is thus not one for the universities alone, and it must be considered against a much broader background than that of finance. As regards the latter, it should be noted, moreover, that in a written answer to a question in the House of Commons on November 4, Mr. Glenvil Hall stated that in assessing grants to the universities, the University Grants Committee recognizes certain standard rates of salary for professors (other than clinical professors). Allowances are, however, made to enable institutions to pay higher rates of salary where the institution considers the rate of salary should for any reason be above the standard. The distribution of this additional remuneration is left entirely to the institution concerned.

These arrangements, Mr. Glenvil Hall added, were made after consultation with the Treasury, and they seem to leave the universities rather freer than Dr. Raven implies to compete with the non-academic world on its own terms. It does not follow, however, that the universities are bound to do so, unless there is real evidence that first-class men are deserting the universities in significant numbers to earn high salaries elsewhere. So far as chemists are concerned, the evidence suggests that even the offer of considerably higher salaries is not attracting to industry all the men needed for research or production. Moreover, Dr. Raven's statement that £1,450 is the maximum salary has been challenged elsewhere; in the civic universities, it is stated that the typical range of professorial salaries is £1,450 to £1,750, apart from the full-time clinical professors, who receive £2,500. Even this range of salaries is not much inducement for a highly trained man with great influence in the community at the peak of his career; and it must be admitted that in spite of the rise in the salaries of university teachers since 1939, neither in leisure nor in money are they, and particularly the professors, as well off as they were before the War. Nevertheless, it is reasonable to ask whether the universities actually know of men who would have taken their more important posts had it been possible to offer another two hundred pounds or so. Such evidence is imperative before the universities take any steps to restore the balance between clinical professors and non-teaching specialists, or between clinical and non-clinical professors, which the recommendations of the Spens Report so obviously upset.

Whatever course the universities adopt, even if they fall back on a general upgrading of all professorial salaries, the repercussions are likely to be far-reaching. Admittedly, comparison between academic salaries and those current in the medical profession is invidious and a poor basis for framing policy. It illustrates, indeed, the embarrassments that may arise from bringing, without careful preparation and forethought, hitherto unplanned and uncoordinated parts of the economy under the ægis of the State. Quite apart from the rise in salaries in a profession already comparatively highly paid given by the institution of the National Health Service, there has simultaneously been a considerable retardation of the operation of the economic factors which would normally restore the balance. Meanwhile, the nation may well find itself in the near future with a plethora of medical and a great scarcity of the scientific workers, technicians and administrators upon whose services industrial productivity and development depend.

The financial incentive is, of course, not the only one. It is often not the most important motive that influences a man or woman in choosing between an academic life or a career in industry, medicine or another profession; but it is essential that at the lower levels, where a difference of two hundred pounds or less may be a decisive factor, the minimum salaries must be such as enable the maintenance of a standard of living compatible with the full discharge of academic responsibilities. The sense of vocation is not entirely lost, and the idea of rendering public service can still influence the choice of profession. Part at least of the immediate task is to dispel the misconceptions which have, for example, made young scientific workers reluctant to enter industry; for few who have gone into modern industry on the research, production or management side have been unable to find satisfaction for their ideal of public service as much as in academic life, the Civil Service or in independent professional practice.

Adequate salaries at the lower levels should be a first consideration in any national policy. If the universities can be satisfied that at those levels there is no longer the risk of some promising scientific worker, for example, who would fill a professorial post with great distinction in a couple of decades if he remained in academic life, being attracted to another career solely on financial grounds, the most important step towards safeguarding the future will have been taken. Nor is the question one for the universities alone. It should also have the attention of the professional bodies, for it is bound up with that question of mobility of staff and the interchange of workers which is now generally recognized as fruitful for creative work. The question of incentives and conditions of work in one particular profession or occupation cannot be considered entirely without reference to those which prevail elsewhere.

These questions need to be examined from a broader angle than has often been done in the past. In a stimulating discussion on the large laboratory in nuclear research at the Princeton Bicentenary conferences, Prof. E. P. Wigner suggested that one important advantage which the university possesses over other institutions is the constant influx of new people to whom the basis of each idea has to be explained and by whom it may be challenged. A comparatively rapid turnover at both the top and the lower levels of at least a part of the staff in a large laboratory or institution might, he suggested, have a vitalizing effect and help to avoid the stagnation which tends to infect such institutions.

Such migration and interchange is, of course, greatly hindered by existing disparities in salary scales, apart from the new tensions which the Spens Report threatens to introduce. Discussions on superannuation schemes have already emphasized the same point, and there are other obstacles such as housing difficulties which are partly financial and partly material. The time is ripe for a broad approach to the whole question from a national point of view. The subject well merits a considered statement by such a body as Nuffield College, giving due weight to the altruism which often determines the choice of profession, as well as to the financial and other material incentives. Such a statement might well be a most important contribution to the solution of the long-term problem of the distribution of the nation's trained man-power in ways which at once afford satisfaction to the idealism and sense of vocation of the individual, and the needs of the community for service in specific fields.

LARGE-SCALE EVOLUTION

Neuere Probleme der Abstammungslehre

Die Transspezifische Evolution. Von Prof. Dr. Bernhard Rensch. Pp. vii + 407. (Stuttgart: Ferdinand Enke, 1947.) 26.20 R. marks.

DR. JULIAN HUXLEY has already directed attention to this book in a short comment published in *Nature* of October 9, p. 562. It is, as he pointed out, a worthy companion of the series of monographs by Dobzhansky, Simpson, Mayr and Huxley himself, which have in the last few years elevated evolutionary theory to a new plane of precision and completeness. It is particularly interesting to be presented at this time with a general discussion which was written in Germany during the War, when communication with English-speaking men of science was at a minimum. The general similarity between Dr. Bernhard Rensch's conclusions and those of the books mentioned above is very striking, and demonstrates that there is a wide consensus of agreement on the new advances in our understanding.

Rensch's work is mainly devoted to that part of evolutionary theory which has always presented the greatest difficulties of interpretation in the past, namely, the large-scale evolutionary changes which relate widely differing species, genera or families. The argument advanced is that, so far as our present knowledge goes, these can be adequately explained by the three main factors—mutation, selection and chance—which produce the minor diversities within species. The book is introduced by a short summary of the evidence for the action of these factors within species and of the nature of the intra-specific differentiation which they bring about. It then passes on to a discussion of the nature of major evolutionary change, which is classified into two broad categories: kladogenesis, or the branching of evolutionary lineages so as to give rise to new types; and anagenesis, or progressive evolution within a lineage.

Rensch's main argument can, perhaps, be summarized in two conclusions: first, that nearly all conceivable types of organisation seem actually to have occurred, which is evidence that the processes are fundamentally under the influence of chance mutation; and secondly, that the individuals which undergo evolution are developmental systems possessing an organisation which conditions the types of change that can arise. These theses are supported by a wide selection of facts drawn from a detailed knowledge of systematics—both of recent and fossil forms—and of many branches of genetics and experimental biology. The reader is left in no doubt that the study of evolution remains, as it was in Darwin's day, the prime field of biology, demanding a universality of knowledge and a power of synthesis which must greatly transcend the narrow limits within which too many biologists are content to be confined.

In the last three chapters, Rensch ventures into even wider fields, and enters on a discussion of the origin of life, and of the evolution of consciousness. The arguments advanced here may not meet with so much general acceptance; but the topic is one to which biologists should more often attempt to contribute. Many of the classical problems of epistemology derive from the elementary knowledge of human sensory physiology which was all that was available to authors such as Hume, and they are bound to appear somewhat differently when seen in the light of our present knowledge of the faculties of man's ancestors.

C. H. WADDINGTON

ELEMENTARY ZOOLOGY IN THE UNITED STATES

Laboratory Guide in Animal Biology

By Robert H. Wolcott and Asst. Prof. Eugene F. Powell. (McGraw-Hill Publications in the Zoological Sciences.) Second edition. Pp. ix+113. (New York and London: McGraw-Hill Book Co., Inc., 1948.) 9*s*.

An Introduction to Vertebrate Anatomy

By Harold Madison Messer. Revised edition. Pp. xxi+475. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1947.) 24*s*. net.

A Concise Comparative Anatomy

By William Henry Atwood. Pp. 413. (St. Louis, Mo.: C. V. Mosby Company; London: Henry Kimpton, 1947.) 20*s*. net.

Textbook of Zoology

By Prof. George Edwin Potter. Second edition. Pp. 948. (St. Louis, Mo.: C. V. Mosby Co.; London: Henry Kimpton, 1947.) 25*s*. net.

THESE four text-books for elementary students illustrate the trends in the teaching of zoology in the United States. As three of them are second editions they have obviously proved successful in their own spheres. The "Comparative Anatomy" by Atwood, although in its first edition, is based on the author's "Introduction to Vertebrate Anatomy", and in some degree, therefore, is not entirely new.

Wolcott and Powell's "Laboratory Guide" is similar to the schedules that most university teachers produce as the result of their experience in dealing with large practical classes. It proceeds by the 'types method', using protozoa, a sponge, cœlenterates, flatworms, a roundworm, a starfish, a mussel, annelids, the crayfish, grasshopper and frog, and treats them in a very elementary way, supplemented by observation of the living animal. The only figure in the book is that of a microscope. Since the student must be taught not only to observe and to dissect, but also to sketch what he sees, a few sample drawings, fully labelled, would be helpful. The book is clearly printed and well bound.

Messer's "Introduction to Vertebrate Anatomy" and Atwood's "Concise Comparative Anatomy" adopt the 'systemic method'. This has the advantage of evolutionary sequence, but the disadvantage that the animal is not appreciated as a whole, and such a method *does* require the study of a single animal to give it balance. The authors have recognized this by adding, for further study, a list of books, many of which are monographs. The preparation of a second edition tempts an author to add new figures, and unless he is careful, the correlation of these with the text and with one another will be neglected. To take an example, Messer figures the arteries and veins of various vertebrates. In the dogfish the arteries are black and the veins white, in *Necturus* and the turtle both are white, in the bird both are striped, and in the mammal they are white. Why could not they be represented similarly in the different classes? Most of the diagrams, however, are clear and well printed; but the blocks of animals in the classification scheme are very much worn. No magnification is given, so that the field mouse appears to be larger than the jack rabbit, and the coney than the dugong. Each chapter ends with a summary, and there is a good glossary. Atwood's book has many diagrams of exceptional merit, but suffers from the same lack of correlation. The English portion of the text is satisfactory; but the Latin terminology is full of errors, for example, corpus restiformus, saccus vasculosis, corpora quadrigemini, and cæcums and appendices!

Potter's general "Textbook of Zoology" was written for rather more advanced students, but is not detailed enough for a British general degree course, although it contains an account of all the phyla. Of the forty-six chapters, eighteen were contributed by collaborators. The types method is used, and the various organs are printed in heavy type so that the paragraphs dealing with them can be easily found. The whole animal kingdom takes up about two-thirds of the book (650 pages) and the remainder has chapters of general interest, such as abnormalities, the endocrine glands, ecology, parasitism, marine zoology, wild-life conservation, genetics and eugenics, embryology, phylogeny and the theory of evolution. A glossary and an exhaustive bibliography are added. The book is thus both informative and interesting, and the author has attempted a compromise between a comprehensive study of the animal kingdom for the student who will proceed no further with the subject, and the necessity for providing the more enterprising and advanced student with the means of extending his knowledge, while stressing for both groups the importance of work in the field and in the laboratory. On the whole, these aims are fulfilled very well. Underlying it the author has in mind the understanding of scientific principles and training in scientific method.

Collaboration has resulted in a lack of uniformity in the standard of the work and in the figures. The section on the frog is unnecessarily elementary, following the more advanced chapters on the vertebrate animal and the two chapters on fishes. In general the line blocks are good, the half-tone blocks so poor that they are sometimes unrecognizable, for example, the bull frog (Fig. 272), Linnæus (Fig. 12), and *Perophora* (Fig. 407). The text has been brought up to date, especially as regards recent work on hormones and vitamins; but here and there a statement causes a shock to the reader, such as this from the chapter on *Amphioxus*: "Ciliated nephridia similar to those of the earthworm lead from the dorsal portion of the coelom to the atrial cavity".

The production is pleasing, and the price (25*s.*) is not exorbitant. N. B. EALES

EARTH HISTORY

The Formation of the Continents by Convection

By G. F. S. Hills. Pp. vi + 102. (London: Edward Arnold and Co., 1947.) 7*s.* 6*d.* net.

THE discontinuous sialic continents floating in the continuous simatic layer and the folded belts of the crust present two of the grandest problems of geology. In this essay, the solutions advanced are these. First, in the early liquid stage of the earth, crystallization began with the sinking of heavy olivine and the floating of light felspar; these floating crystals were carried by convection to the poles to form clumps which, as the liquid magma became more viscous and convection ceased, were then moved to the equator by the Eötvös force. During these operations, radioactive substances, concentrated in the felspathic material, heated the underlying olivine-layer which, thus expanded, elevated this material above the oceans to make the Laurasia and Gondwanaland of the palæogeographer.

The second problem is solved as a consequence of this expansion; the continental masses, pegged down to the Pacific rim, are domed up by uprise of basaltic material which, finding its own level, escapes around the rim, creasing up the continental and geosynclinal margins into the fold belts and, spreading over the floor of the present Pacific, carries with it fragments of continental material that formed, for example, New Guinea, Fiji and other islands. This gigantic basalt flow was responsible for the Cenomanian Transgression and a variety of other events.

With these two mechanisms in mind, the author discusses the Atlantic rift, the roots of mountains, the origins of fiords, the cause of the Quaternary glaciation, the salt in the sea and the absence of fossils in the Pre-Cambrian rocks, and finds many of the hard problems connected with these diverse topics more amenable.

Inquiries such as these into the mechanisms of the earth are naturally of interest to the geologist, who is usually not qualified to make them—he leaves it to the mathematician or geophysicist. The author views a great many geological operations in a different way from the geologist. His conception of the crystallization of magma, the formation of granite, the production of gneissose texture, the history of the fold-belts—to name a few special points—and his general use of the geological time-scale, are not those of the geologist dealing with the detailed anatomy of the crust. But still the author's proposals must be considered alongside those of Daly and Sir George Darwin, when the geologist comes to contemplate the bearing of his mass of detail on the grand problems of earth-history. H. H. READ

FRUIT GROWING AND STORAGE

Harvesting and Storing Garden Fruit

By Raymond Bush. Pp. 162+16 plates. (London: Faber and Faber, Ltd., 1947.) 12*s.* 6*d.* net.

WHEN Mr. Raymond Bush sits down to write a book or an article, one may be sure that the result will be well worth the gardener's reading. There is always much wisdom, not untinged by humour, much of a life-time's accumulated experience and, usually, something at least to make one doubt or even disagree. His new book is no exception; no fruit-grower could read it without enjoyment and without learning a great deal; but some at least would feel a sense of disappointment. The book was obviously intended originally for the amateur fruit-grower—its title alone leaves no doubt on that point; but the author's enthusiasm for his subject carries him outside his field, and some of his suggestions would be beyond the means or the needs of all but the wealthiest of amateurs. The suggestion, for example, that quick-freezing of fruits and vegetables could be practised in the home is surely misleading, to say the least, when one considers that for satisfactory preservation an initial temperature of about − 30° F. is necessary. On this subject, details of the method of processing seem of little value or interest to the public for whom the book is intended, while for anyone seriously considering factory-production the information would be hopelessly meagre.

Taken by and large, it is a curiously compounded volume; one is left with the feeling that the author set out to write a book specifically to the title, and then, having found that it was of insufficient size, added five chapters at the beginning containing random dissertations on soils and climates for fruit-growing, manuring, pollination and other cultivational problems, all full of good advice and wise comment but having little direct bearing on the real subject.

On the central matter of storage, one cannot again help but feel a sense of disappointment. The storage of fruits has been a matter of such intensive scientific research, research which is not so difficult to 'put over' to the layman, that some attempt might be made to explain the physiological principles involved. The meaning and significance of the 'climacteric' in fruit ripening and storage is surely worth more than two paragraphs of explanation. Again, if the description of the quick-freezing process was worth inclusion, something might have been said of gas-storage, even if only to make the layman aware of the possibilities and limitations of the process.

At the end, the author again adds four chapters, which one would not expect from the title, on jam-making, bottling and canning, wines and fruit-juices. Here, at least, is a field in which the amateur can practise, and if the book stimulates a revival of the old art of home cider-making it will, on that alone, achieve much. The descriptions of home-made fruit wines fill one with the desire to start without delay on one's own 'brewery'; but further reading discloses the need for impossible quantities of that rare commodity, sugar, and regretfully one abandons hope until more spacious times come back.

Despite the criticisms which have been made, the book, as has been said, is one which all interested in fruit-growing can read with profit and enjoyment.

R. H. STOUGHTON

ELECTRONIC APPLICATIONS OF GERMANIUM

CRYSTAL rectifiers, the essential constituents of which are a metal and semiconductor in contact, are of two types, large-area contact rectifiers, such as copper oxide or selenium rectifiers, and point-contact ones, such as the germanium or silicon type. In both types the semi-conductor, which contains certain impurities, is in the form of a slab making contact on both top and bottom with the metal. For large-area contact rectifiers, rectification is obtained by making the intrinsic rectifications of the two metal-semiconductor contacts of different values, and for the point-contact rectifiers by making the area of one contact, usually the upper one and consisting of a small point at the end of a wire of metal such as tungsten ('cat's whisker'), very much smaller than the area of the other contact, the base electrode.

Germanium High Back-voltage Rectifiers

With the extension of radio communication to ultra-high frequencies, the use of point-contact crystal rectifiers in telecommunication circuits has become an established practice. The silicon rectifier, which is most suitable for ultra-high frequencies, is limited in that it can withstand only a small inverse voltage. The germanium crystal rectifier, in a form which has recently been developed[1,2,3], is less liable to overload. It can withstand a peak inverse voltage of 80 volts and deliver a maximum continuous current of 50 milliamperes; and although its frequency response is inferior to that of silicon, it is greatly superior to that of the metal-oxide rectifier. Its small weight and size (¼ inch diameter and ⅝ inch long) makes it particularly useful as a component in portable or miniature electrical equipment. As a detector or rectifier it can replace the vacuum diode, with the considerable advantage that, being a non-heating device, A.C. hum, noise, and thermal delay, from which all hot-cathode devices of the vacuum type suffer, are absent.

The germanium crystals used in these high back-voltage crystal rectifiers are excess (n-type) semiconductors, and are obtained from ingots formed *in vacuo* and slowly cooled. They require to be lapped in order to introduce large flow forces, which probably change the surface layers, and to be etched, the action of which is not clearly understood but which is said to improve the back voltage.

The Transistor

It is with germanium prepared in this fashion that J. Bardeen and W. H. Brattain, of the Bell Telephone Laboratories, in the course of a general investigation, initiated and directed by W. H. Shockley, on the properties of semiconductors, have developed a new three-element electronic device, called by them a 'transistor' (transfer-resistor) or 'semi-conductor triode'. This can be employed as an amplifier or oscillator and can replace the vacuum triode in most electronic circuits. The device, which consists of a metal cylinder, about an inch long and of the thickness of a pencil, containing the germanium and its three electrodes, was demonstrated with great success recently at a Press conference in New York. The transistor was used to amplify telephone and television signals, and a standard-model radio receiver, with transistors in place of the ordinary radio valves, operated quite satisfactorily. A standard frequency note generated by an oscillatory circuit employing transistors was also produced.

The construction and basic principles of operation of the transistor have been described by its discoverers in two letters communicated by them to the *Physical Review*[4]. In place of the single 'cat's whisker' of the crystal rectifier, two fine wires (both tungsten and phosphor-bronze have been used) make contact with the upper surface of the germanium block. These electrodes, the emitter and collector, are about 0·005–0·025 cm. apart. The third electrode, which is a large-area low-resistance contact, makes contact with the base of the block. Both the emitter and collector, when connected separately with the base, have characteristics similar to that of the high back-voltage rectifier. With a suitable positive bias on the emitter and negative bias on the collector relative to the base electrode, a signal introduced between the emitter and the base appears in amplified form between the collector and the base. Amplifications up to 100 times, that is to say, a gain of 20 decibels, have been obtained.

The transistor uses less power than a vacuum tube, has an output of 25 milliwatts and can operate at frequencies up to 10 megacycles per second. The collector has a high impedance and can therefore be matched to a high-impedance load. Being an excess (n-type) semiconductor, the main body of the germanium conducts electricity by excess electrons; but, as tests described in the second of two letters confirm, there is a thin layer next to the upper surface of the germanium which is of defect (p-type) positive-hole conductivity. Thus a current of positive-holes flows from the emitter and spreads over the surface of the semiconductor. Since the sign of the collector bias is such as to attract the positive-holes, a large part of the emitter current flows to and enters the collector. The collector has a high impedance for the flow of electrons into the semiconductor, but little or no impedance to the flow of positive-holes, so that for a signal voltage which varies the emitter current, there is a corresponding larger variation in collector current, producing the observed amplification.

The nature of the excess conductivity of the surface layer was investigated by means of probe measurements of the potential in the vicinity of a point contact on the plane surface of a thick block of germanium. Various surface treatments, in addition to the etch usually employed for crystal rectifiers, were used in different tests. The existence of the (p-type) conducting layer at the surface was confirmed, but the conditions very close to the point contact (within 0·01 cm.) were found to be complicated.

The transistor is not yet in production, but its simplicity, small size, performance, long life, and probably low cost when mass-produced, should find many applications in all forms of electronic equipment.

Non-rectifying Germanium

Following closely on the announcement of the transistor with its (p-type) defect surface layer, W. E. Dunlap and E. F. Hennelly, of the General Electric Company research laboratories, New York, report[5] the preparation of germanium of rather unique properties, of which the most striking is the almost complete absence of surface rectification at the germanium–metal contact. The germanium ingots were prepared by melting germanium powder under a pressure of less than 10^{-4} mm. of mercury, and ten-point, plane-welded contact rectifiers were made from one ingot. The units were weakly (n-type) excess semiconductors at room temperature, where their average rectification ratio for 20 volts was 3·54, and (p-type) defect semi-conductors at −196° C., where the corresponding ratio was 1·22. For small voltages the rectification was negligible at both 25° and −196° C.; but for 20–100 volts the rectification factor increased to the order of 2. This is attributed not to a true rectification but to possible heating and consequent inhomogeneity in the germanium. Hall-effect measurements showed that the transition from n to p takes place at 70° C. The room-temperature resistivity, 17·8 ohm. cm., was increased by some 20 per cent by the application of a magnetic field of several thousand gauss, and the Hall coefficient, 514,000 E.M.U., decreased by about 30 per cent for an increase of field of approximately 10,000 gauss. The high magneto-resistance and variation of Hall coefficient with magnetic field, in spite of the apparently high degree of homogeneity of the germanium, is the second point of interest. It is suggested that these effects are intrinsic or else the inhomogeneity is on a scale small compared with the dimensions, about 0·0002 inch, of the point-contact, and further work is in progress to test these ideas.

NEW LIGHT ON THE ORIGIN OF MONEY

By DR. PAUL EINZIG

MATERIAL produced by recent ethnological research calls for a revision of the hitherto generally accepted 'classical' conception of the origin and early evolution of money. That conception may be briefly summarized as follows: Barter developed as and when original communism (tribal ownership of the means of production) gave way to private property, and self-sufficiency of economic units gave way to division of labour. Money developed after the progress of division of labour and the growing complexity of the economic system had reduced barter to absurdity. The primitive forms of money originally adopted were gradually replaced by more advanced forms. Eventually, the functioning of advanced money economy led to the development of credit economy.

This conception is all but universally endorsed by economists, and is expressed briefly and superficially in most text-books on money. Yet in the light of ethnological and historical research it must be denounced as fundamentally false. Paradoxical as it may seem, it is nevertheless a fact that barter existed before the development of division of labour and private property in the generally accepted sense of these terms; that money originated long before the complexities of progressing economies had reduced barter to absurdity; that the origin of money was due to a large extent to non-commercial factors; and that credit existed already before money came into being.

According to the classical conception of economic history, foreign trade existed before home trade; barter first developed between tribes specializing in different cultures, while within the tribes themselves it only developed after the adoption of a certain degree of division of labour. This conception is entirely erroneous. There was ample scope for barter within a pastoral, agricultural, hunting or fishing tribe. As has been ascertained, members or households of a tribe specializing in one single culture are, in fact, in the habit of exchanging systematically their products against each other. For one thing, even though the entire tribe may be pastoral, that does not necessarily mean that they breed the same kinds of animals. Even if they do, there is, in any event, ample scope for exchanging young animals against old ones, good quality stock against inferior stock, etc. Likewise in an agricultural community there is ample scope for exchanging various agricultural products against each other.

There is ethnological evidence also for the existence of barter in communities where means of production constitute tribal property. Once the proceeds of production are distributed they become private property, and there may be occasion for bartering the products against each other. When the chief of a warrior tribe distributed among the tribesmen the proceeds of a successful raid or the tribute paid by subject tribes, the objects thus distributed became the private property of the recipients and provided occasion for barter among each other long before the development of private ownership of the means of production. In particular the enslaved captives provided material for systematic barter.

The conception that money came to be adopted as and when progress of division of labour had made it intolerably inconvenient to trade by means of barter is regarded as axiomatic by the overwhelming majority of economists. Yet there is ample ethnological evidence to prove that in a large number of communities barter continued long after the adoption of some form of standardized means of payment for non-commercial purposes. In many primitive communities in the Pacific area or Africa, internal trade is, or was until quite recently, conducted almost entirely by means of barter even though standardized means of payment were in use for certain non-commercial purposes, such as payment of bride price, contributions to religious sacrifices, subscriptions to secret societies, payment of tribute, ransom, blood money, etc. While it is known to ethnologists, it is not realized by the overwhelming majority of economists that, in primitive communities, such non-commercial payments are incomparably more important than commercial transactions proper. They wrongly believe that a community at an early stage of its economic evolution does not feel the necessity for the adoption of money unless and until barter has become too inconvenient owing to the growing variety of goods and services to be exchanged against each other.

In reality, barter is not nearly so inconvenient a system in a primitive community as is assumed by economists who look upon it through modern eyes. The instances quoted by economists to illustrate the difficulties that were eventually supposed to have led to the adoption of money are usually taken not from the internal life of primitive tribes but from the experience of European travellers in dealing with them. There was the much-quoted experience of Cameron who, in order to be able to acquire an urgently needed boat in Tanganyika, had to exchange his brass wire against cloth, then cloth against ivory and finally ivory against the boat. There was also the well-known experience in Indonesia of Wallace, who had to do without dinner whenever vendors of food did not happen to want his goods. Mademoiselle Zélie, of the Théâtre Lyrique, Paris, complained in a much-quoted letter that her fee for a concert on one of the Society Islands, consisting of three pigs, twenty-three turkeys, forty-four chickens, five thousand coconuts and considerable quantities of bananas, lemons and oranges, was of little use to her. All these and many other instances may appear to the modern reader as a convincing proof that barter is an impossible system. Yet these instances only illustrate the difficulties and anomalies that are apt to arise through contact between two different civilizations. The natives of the communities visited by Cameron, Wallace and Mademoiselle Zélie were quite capable of making their own arrangements to ensure the smooth working of a system which, though far from ideal, suited their primitive requirements tolerably well. The fact that even culturally advanced communities with relatively developed economies, such as Ancient India and Ancient Egypt, conducted their trade mostly by barter shows that the inconveniences of that system have been grossly exaggerated by modern writers.

The development of some form of standardized means of payment must have preceded in most communities the achievement of a stage in the progress of division of labour when barter became impracticable. Long before that stage was reached, there already existed some form of money used regularly for non-commercial purposes. Nevertheless, the communities concerned continued to barter, not because they knew no better, but because they preferred to exchange goods and services against each other rather than against money. It was largely because the non-commercial purposes for which money was employed ensured a steady demand for the monetary objects that they gradually became favourite media of barter and ended by becoming media of exchange. It seems reasonable to assume, therefore, that money first developed to serve matrimonial, political or religious payments and was only later adopted gradually for commercial purposes. Possibly it was adopted as commercial means of payment even before division of labour made barter impossible.

Long before this stage was reached, an advanced credit economy developed in many primitive communities. During recent years ethnologists have described many communities in which trade was transacted mostly by barter, but which possessed, nevertheless, a highly involved credit system arising from the non-commercial use of some standardized means of payment. Thus in the New Hebrides there is a most elaborate and extensive credit system in terms of pigs, arising from the sacrificial use of the animals[1]. Shell strings required for subscriptions in secret societies formed the basis of a veritable inverted pyramid of credit system on the Banks Islands[2]. Payments in connexion with marriages resulted in a highly involved system of indebtedness in dogs' teeth currency among the Manus of the Admiralty Islands[3]. On Alor, in Indonesia, everybody is both a creditor and a debtor in a complicated system of reciprocal indebtedness in terms of bronze drums and gongs which form an indispensable part of the bride price[4].

The existence of a highly developed credit system in Babylonia many centuries before the adoption of coinage, during a period when the currency consisted of barley and uncoined silver, is an instance of the evolution of credit prior to the evolution of modern money.

Barter, by its nature, gave rise to a credit system before the adoption of money. This was not realized by some economists, who, however distinguished in their own lines, were unacquainted with the elements of anthropology. John Stuart Mill's picture of the tailor on the verge of starvation trying frantically to find a baker who happened to be in need of a jacket, in order to secure his daily bread in exchange for it, is a characteristic instance in this respect[5]. Fortunately for themselves and for the progress of mankind, primitive man had enough common sense to overcome the difficulty, which existed in Mill's imagination, that the tailor would not want as much bread at a time as would be worth the coat and that the coat could not be divided. In fact, the tailor could easily make arrangements with the baker to secure the supply of bread over a period in return for the sale of the coat. This is what is done regularly in present-day primitive communities. According to ethnological evidence, blacksmiths and other artisans are paid after harvest for goods and services supplied between harvests.

To some extent the development of primitive money actually does away with the necessity for credit system that was indispensable in a barter economy owing to the discrepancies between the value of the objects exchanged and the time-lag between their delivery. Thanks to the adoption of some object for monetary use, blacksmiths can now collect payment immediately instead of having to wait until the next harvest; and John Stuart Mill's imaginary tailor would have been able to sell his coat to the baker against cash payment instead of granting credit in terms of loaves.

Many of the above facts and conclusions may appear elementary to ethnologists. They are ignored, however, by the overwhelming majority of economists. It is of the utmost importance to establish closer co-operation between the two branches of learning for the benefit of both. It is to the interest of monetary economists to study more closely the origin and early phases in the evolution of money, instead of accepting as axiomatic the vague and out-of-date observations on the subject in Adam Smith's "Wealth of Nations". They have to become acquainted with the material produced by ethnologists. The latter, in turn, are in need of better acquaintance with the theoretical rules of monetary economics. In the absence of such knowledge, they are unable to make adequate use of their opportunities to study on the spot such primitive monetary systems as still exist. Their findings are apt to be exasperatingly vague. While asserting in general terms that certain material serves as the currency of a certain community, they very often fail to state precisely which monetary functions the material in question performs and to what extent. Above all, they are not qualified to ascertain if, and to what extent, the behaviour of primitive money conforms to the accepted rules of monetary theory. As primitive monetary systems are disappearing fast, it is of the utmost importance that ethnologists engaged in field-work should equip themselves with the necessary knowledge of monetary theory while there is still a possibility of investigating the functioning of the primitive monetary systems which have survived to our day.

VITAMINS AND ANTI-VITAMINS

AN interesting discussion on "Anti-vitamins in Food", arranged by the Nutrition Society, took place on October 23 at the Royal Society of Arts. Sir Edward Mellanby, who might justly claim to be the originator of the modern concept of anti-vitamins, was chairman. In his introductory remarks he pointed out that the 'anti-vitamin' or 'toxamin' theory is now some twenty years old, although his early claims that cereals must contain substances which antagonize vitamin D had not been immediately accepted. Later work, however, in identifying phytic acid as an anti-calcifying factor, had placed the existence of anti-vitamins beyond dispute. Considerable progress is now being made towards an understanding of the general principles underlying the mode of action of the anti-vitamins, and both their significance as dietary factors and their potentialities as therapeutic agents are clearly recognized.

Natural and Artificial Anti-vitamins

Dr. L. J. Harris recalled that Eijkmann, who shared a Nobel Prize with the late Sir Frederick Gowland Hopkins for the discovery of vitamins, resorted to what amounted to an 'anti-vitamin' theory to explain the results of his experiments on avian polyneuritis. Since a diet of polished rice caused polyneuritis, while rice polishings cured this condition, he assumed that the rice contained a toxin and the polishings an antidote. Hopkins, on the other hand, proved the reality of 'deficiency diseases', in which injury is caused simply by the absence of a vitamin from the diet, and not by failure of the vitamin to neutralize a dietary toxin. While Hopkins' conclusions have proved substantially correct, it is now realized that the adequacy or inadequacy of a diet in regard to a particular vitamin may often be influenced by the other constituents of the diet. Since the requirement of the organism for vitamin B_1 has been found to be proportional to the carbohydrate intake, we may regard the starch present in Eijkmann's polished rice as being antagonistic to the vitamin B_1 present in the polishings. In this limited sense, therefore, it may be considered a toxic substance.

The important work of Mellanby on the rachitogenic properties of cereal products, however, indicated that some foods contain substances, other than their major components, which antagonize the action of vitamins. Another important advance resulted from the demonstration by Fildes and Woods that the sulphonamide drugs owe their bacteriostatic action to their biological competition with *p*-amino-benzoic acid, a compound with a similar chemical structure which has since been recognized as a vitamin. The sulphonamides may therefore be regarded as artificial anti-vitamins, and, on the same principle, analogues inhibiting the action of most of the other vitamins have now been synthesized. Although it was not intentionally chosen as an anti-vitamin, the familiar insecticide 'Gammexane', or hexa-chloro-benzene, presumably owes its activity to its competition with the vitamin inositol, the corresponding hexa-hydroxy compound.

In estimations of vitamins in foodstuffs by biological tests, the results obtained will depend not only on the amounts of vitamin present but also on the amounts of anti-vitamin, as well as on the presence of substances which assist the vitamin in its absorption and utilization, and many other factors. Chemical tests, on the other hand, tell us how much vitamin is present, without enlightening us as to its degree of availability to the animal. Since both chemical and biological methods give results which are perfectly correct, within the limitations recognized in each case, it is obviously essential that in quoting vitamin values for foodstuffs the method used should be clearly stated.

Anti-B-vitamins

The numerous B-vitamins in themselves present a very complicated picture, which is made even more complex when we extend our studies to the corresponding anti-vitamins. Many B-vitamins, moreover, are synthesized by the intestinal bacteria, in amounts which differ widely in different animals, with the result that anti-vitamins may either affect the organism directly or through the agency of the intestinal flora. Altogether, Dr. E. Kodicek has enumerated five ways in which the action of B-vitamins may be inhibited, including (1) failure of intestinal absorption, (2) the destruction or inactivation of the vitamin by toxic substances or bacteria, (3) the inhibition of bacteria producing the vitamin by antagonists or the absence of an essential metabolite, (4) the displacement of the vitamin from the tissues by analogues, and (5) exposure of the organism to special-stresses, such as infections, pregnancy, and a bad balance of the major components of the diet.

Various types of 'toxamins' may oppose the action of B-vitamins, but the term 'anti-vitamin' is perhaps best reserved for the structural analogues, which have already been synthesized in relation to aneurin, nicotinic amide, riboflavin, vitamin B_6, pteroyl glutamic acid, pantothenic acid, biotin, choline and inositol. Several natural toxamins have also been reported, including the thiaminase in live yeast which destroys vitamin B_1, a factor in maize which antagonizes nicotinic amide, the avidin of raw egg white which inactivates biotin, and the lycomarasmin of wilted tomato plants which antagonizes the bacterial growth-factor, streptogenin.

Rachitogenic and Hæmorrhagenic Toxamins

Phytic acid, a phosphorylated derivative of inositol, is the best known anti-calcifying agent in foodstuffs. Prof. R. A. McCance pointed out that evidence of the rachitogenic properties of cereal products was advanced by Mellanby in 1920; but it was not until about ten years later that Bruce and Callow found that phytic acid interferes with the absorption of calcium. Harrison and Mellanby then demonstrated that this substance had the same effect as cereals in causing rickets in dogs, while

McCance and his colleagues found in human feeding trials that the absorption of calcium was less efficient with wholemeal bread than with white bread as the main constituent of the diet. The addition of calcium to National flour was therefore undertaken in order to compensate for the increased amounts of phytic acid which resulted from the higher extraction-rate.

Unidentified rachitogenic agents have also been encountered in animal feeding-stuffs. Yeast is a valuable source of proteins and B-vitamins for pigs; but Dr. S. K. Kon and his colleagues have found that it causes rickets unless cod-liver oil, or some other source of vitamin D, is also given. Dr. T. K. Ewer has observed rickets in sheep reared in the southern island of New Zealand, where young green cereals are used as fodder. The condition responds to treatment with vitamin D; exposure to sunlight, however, is not effective, the tendency to rickets being greatest when good weather causes a rapid growth of the fodder.

Fatal hæmorrhages, associated with a prolonged blood-clotting time, have long been known to occur in cattle fed upon defectively cured sweet-clover, and Link and his colleagues identified the toxic agent as dicoumarin. Since full protection against the action of this substance may be secured by the administration of vitamin K, it may be regarded as a typical toxamin in the sense implied by Mellanby. Dr. P. Meunier, of Lyons, has studied the quantitative balance between hæmorrhagenic agents and vitamin K in the rabbit. Several synthetic analogues, including phenyl indanedione, have been found to cause increased clotting times, although they are generally less active than dicoumarin.

Imbalance of Fat-soluble Vitamins

Under this heading, Dr. T. Moore discussed the effects of toxic overdosing with one vitamin, and also the effects of deficiency or excess of various nutrients on the activity of the fat-soluble vitamins. Thus, massive overdosage with vitamin A leads in rats to skeletal fractures and hæmorrhages which are reminiscent of scurvy, while this disease has also been diagnosed in an American child given absurdly large doses of vitamin A. It has been reported that vitamin A deficiency causes a secondary deficiency of vitamin C in rats and silver foxes; but the significance of this vitamin in both deficiency and excess of vitamin A remains undecided. Hypervitaminosis A in rats, however, undoubtedly leads to a prolonged blood-clotting time which can be corrected by giving vitamin K.

The demands of the organism for carotene or vitamin A may be influenced by many factors. Extensive animal experiments have indicated that vitamin E, a powerful antioxidant, protects vitamin A from destruction in foodstuffs during storage, in the products of their partial digestion passing through the intestinal tract, and in the tissues of the consumer. In the human subject the habitual use of medicinal paraffin may seriously interfere with the absorption of carotene. Early work by Mellanby indicated that certain cereal products, and also ergot of rye, may emphasize the effect of vitamin A deficiency in causing nervous lesions, which his later work has associated with disordered growth of bone.

Massive overdosage with vitamin D causes excessive calcification, and doses approaching the toxic level have been found by Charpy and by Dowling to be valuable in the treatment of cutaneous tuberculosis.

Deficiency of vitamin E in experimental animals causes not only reproductive failure but also many other lesions including muscular dystrophy, brown pigmentation of the uterus and adipose tissues, exudative diathesis, encephalomalacia, renal abnormalities and dental depigmentation. Most of these lesions are increased in severity by an inadequate protein allowance, and by the inclusion in the diet of cod-liver oil or other highly unsaturated fats. Conversely, the lesions may be avoided or reduced in severity by removing fats from the diet, and by including adequate amounts of protein, choline, methionine and inositol. In general, therefore, liability to the effects of vitamin E deficiency is increased by the consumption of readily oxidizable fats, and decreased by adequate dietary supplies of the lipotropic factors which facilitate the mobilization and transference of fats.

Mr. A. L. Bacharach summarized the day's proceedings, and expresssed his satisfaction in the success of the meeting in bringing together a mass of information on an interesting and important subject.

OBITUARY

Sir John Fryer, K.B.E., F.R.S.

AGRICULTURAL science has suffered a severe loss by the death on November 22 of Sir John Fryer, secretary of the Agricultural Research Council, at the age of sixty-two. The news came as a great shock to his many friends both in scientific and administrative circles.

John Claud Fortescue Fryer was born on August 13, 1886. His family had been farmers in Cambridgeshire and Huntingdonshire for generations, and his early years were spent at Chatteris in the fenlands; he was always happy to return to the East Anglian countryside. He was at school at Rugby and went on to Gonville and Caius College, Cambridge, where he took a first class in the Natural Sciences Tripos and a little later was elected a fellow of the College. He already had a good knowledge of British insects and, like his father and grandfather before him, was a keen collector and field naturalist. Some years abroad followed. He joined the Percy Sladen Expedition to Aldabra Island, in the Indian Ocean, and wrote a valuable account of the natural history of the island; he also spent some time in Ceylon where he worked on the genetics of the butterfly *Papilio polytes*. On returning to England, Fryer was appointed entomologist to the Ministry (then Board) of Agriculture, and devoted himself to the study of insects of economic importance in agriculture and horticulture. It was a new post and he started work in an office in Northumberland Avenue without laboratory accommodation or equipment. After a pioneering period, a small staff of entomologists and plant pathologists was recruited and the Ministry's Plant Pathology Laboratory established. Accommodation was found for a time at Kew, and in 1920 a move was made to permanent quarters at Harpenden, where Fryer made his home. As director of the Laboratory, he took a leading part in dealing with a great variety of problems and inquiries concerning insect and other pests of crops, in fostering and initiating research on control measures, and in establishing an efficient advisory service in these subjects throughout Great Britain. One of his major problems was the continually increasing threat of the introduction into Britain of the Colorado beetle after its establishment on the Continent of Europe.

In 1941, the Ministry formed the Agricultural Improvement Council to act as a bridge between science and practice in agriculture, and Fryer became its first secretary. His work for some years had involved close contacts with the Agricultural Research Council, and in 1944, following the death of Dr. W. W. C. Topley, he accepted appointment as secretary of the Council. It was with some misgiving that he undertook this onerous task, for it meant continuous office-work in London, and he knew that there would be little or no time for his entomological interests.

In addition to his scientific attainments, Fryer possessed high administrative ability, and his appointment was quickly justified. His practical knowledge of farming, acquired in his early days, combined with a long experience of the application of scientific method in agriculture, admirably fitted him for the work. Moreover, he had, to a rare degree, the capacity to see and state clearly and succinctly the essential points of any problem, and many who sought his advice could testify to his clear-sighted, logical and helpful discussion of their difficulties. He was especially good in committee, where his sure grasp of essentials and his tactful guidance often brought a rambling discussion to a point.

Fryer was a real countryman and naturalist and a keen fisherman. He was at his best on a collecting expedition in some remote part of the country, and the briefest holiday was spent, if possible, where he could search for specially interesting or rare insects. He had fine collections of British Lepidoptera, Coleoptera and Hemiptera–Heteroptera and was an expert on the Microlepidoptera. He took great interest in the conservation of the British fauna and flora and was an active member of the Society for the Promotion of Nature Reserves and of various committees of the National Trust. He served as president of the Association of Applied Biologists and of the Royal Entomological Society; he was elected a fellow of the Royal Society in 1948. His official services were recognized by a knighthood in 1946.

In 1919, he married Constance Joan Denny-Cooke, of Bergh Apton, near Norwich, who, with a son and daughter, survives him. He was buried at Bergh Apton.

C. T. GIMINGHAM

NEWS and VIEWS

The National Physical Laboratory, Light Division: Mr. T. Smith, F.R.S.

On his retirement last July, Mr. T. Smith completed a period of forty-one years service at the National Physical Laboratory, where he was in charge first of the Optics Section of the Physics Department and later of the newly created Light Division. The long series of investigations on geometrical optics which have established Mr. Smith as a leading authority in the subject were begun a few years after he entered the Laboratory with a paper to the Optical Society entitled "Practical Optical Calculations". This was the key for much of his later work. His outstanding contributions have been to the theory of algebraic, as distinct from trigonometric, methods of optical design, and in the development of methods of computation based on the use of calculating machines. A feature of many of his later papers has been the masterly application of matrix methods to optical problems. As is so often the case when alternatives to old-established procedures are offered, the adoption of Mr. Smith's design methods in the industry has been slow; but there are now signs that their value is being appreciated. Mr. Smith's work was recognized by his election to the Royal Society in 1932, and he has held the office of president both of the earlier Optical Society and the Physical Society. The younger workers in his subject recall with appreciation the care he always took that they should have the fullest opportunity to develop their views however unorthodox or immature. It is appropriate that the council of the Physical Society should have invited Mr. Smith to deliver the sixteenth Thomas Young Oration; this he has agreed to do in June 1949.

Dr. L. A. Sayce

Dr. L. A. Sayce, who has succeeded Mr. T. Smith as superintendent of the Light Division at the National Physical Laboratory, is fifty years of age. After serving in the Honourable Artillery Company in the First World War, he went to the University of Durham to study chemistry, taking honours in 1922, when he was awarded the Saville Shaw Medal. He remained at Durham carrying out research in inorganic chemistry, was awarded his Ph.D., and in 1927 was appointed University lecturer in chemistry. He remained at Durham until 1940, carrying out during this period considerable fundamental work in inorganic chemistry, instrument design, chemical kinetics and photography.

In 1940 Dr. Sayce joined the Ministry of Home Security to initiate a research group in connexion with camouflage, where he did excellent work until 1943. He was then transferred to the Ministry of Supply to take charge of alginate research. Unfortunately, he fell seriously ill soon after receiving this appointment and was away from active work for a year. On recovery he was appointed to the Scientific Research Department of the Admiralty as a principal experimental officer, and in this capacity he was responsible for considerable advances in the development of all kinds of instruments for laboratory use in the Admiralty experimental establishments. In particular he did excellent work in the applications of high-speed photography for laboratory purposes. On the re-organisation of the Admiralty Scientific Service in 1946, he was appointed assistant director of physical research. Dr. Sayce has earned a very high reputation in a wide field of science, and he brings to his new appointment a keen appreciation of the value of fundamental research and an exceptional ability to plan and supervise it.

Zoological Society of London: Mr. G. S. Cansdale

Mr. G. S. Cansdale has been appointed superintendent of the Zoological Society's Gardens in Regent's Park, London, in succession to Dr. G. M. Vevers, who retired on December 15 (see *Nature*, November 6, p. 727). Mr. Cansdale was educated at

St. Edmund's Hall, Oxford; he graduated in forestry and afterwards obtained a research degree for work on black poplars and their hybrids. He was appointed to the Colonial Forest Service in 1934 and served in the Gold Coast from then until 1948. During these years he took full advantage of the opportunities of studying the local fauna and made large collections of reptiles, birds and small mammals for the London Zoo, many of which were new to the collection; in addition, he made extensive collections for the British Museum (Natural History). He has published various popular articles dealing especially with small mammals and their ecology, and is the author of "Animals of West Africa", a general account of the more common mammals and reptiles of that region. In addition to being a keen naturalist, Mr. Cansdale has the advantage of practical experience in keeping live animals, for he and his wife maintained a private collection in Africa and were successful in the rearing and maintenance of a wide range of species, including some which are very difficult to adapt to a life in captivity, with the necessary dietary modifications involved. This experience will be of value in dealing with the many problems which arise in connexion with the maintenance of such a varied collection of animals as that in Regent's Park.

Physics To-day

THE avowed purpose of the American Institute of Physics is "the advancement and diffusion of physics and its applications to human welfare". For the research worker, the teacher, the theoretical or experimental physicist, and the investigator engaged in pure or applied science, the Institute or its member societies publish eight journals of very high merit. They are the well-known *Physical Review, Review of Modern Physics, Journal of the Optical Society of America, Journal of the Acoustical Society of America, American Journal of Physics, Review of Scientific Instruments, Journal of Chemical Physics* and the *Journal of Applied Physics*. To these, in order to fulfil an ever-growing demand for a medium for relatively non-technical surveys of physics progress, there has recently been added *Physics Today*. This new monthly magazine (published by the New York American Institute, May 1948; 50 cents) is described as "a general-interest journal on physics", and its editor is Dr. D. A. Katcher.

The first four numbers of *Physics Today* are very well produced and contain some excellent articles, besides regular features such as book reviews, Institute and Journal notes, and notes from abroad giving details of physics progress in Italy, Great Britain, Scandinavia and elsewhere. Of the articles, "A Newsman Looks at Physicists", by Stephen White, in the May issue is highly to be commended. It is packed with sound advice to the physicist who is called upon either to write for the general Press or to describe his work to some enterprising reporter. Of particular interest to British readers will be a brief but informative report in the May issue by D. L. MacAdam on the 1947 International Conference on Colour Vision held at Cambridge, England, and an illustrated account in the July issue, by the general secretary of the Royal Institution, T. Martin, of the Royal Institution Christmas Lectures. Other articles include: "Trends in American Science", by Vannevar. Bush; "The Reality of Neutrinos", by Prof. G. Gamow; "Detecting Atomic Particles", by Prof. S. A. Korff; and "Helium, the Unruly Liquid", by Prof. L. Tisza. Perhaps the best way to summarize the scope and policy of the magazine, which assuredly has come to stay, is to quote from the editorial of the first number. " 'Physics Today' is for the physicist, to inform him in comfortable, everyday language of what goes on and why and who goes where. But it is also for the chemist, the biologist, and the engineer, to tell them of the science towards which they are driven by so many of their investigations; it is for the student, the teacher, the lawyer, the doctor, and all who are curious about physics; it is for the administrative officials who deal with research; it is for editors and writers whose profession puts them midway between what is done and how it should be reported".

World Power Conference: 1950 Meeting in London

As already announced (see *Nature*, June 26, p. 1,005), the Fourth World Power Conference will be held in the building of the Institution of Civil Engineers, London, during July 10–15, 1950, and the theme of the Conference will be "World Energy Resources and the Production of Power". Sir Harold Hartley will be chairman of the Conference. The technical programme of the Conference has just been published, and copies may be obtained on application to the General Secretary, Fourth World Power Conference, 201–2 Grand Buildings, Trafalgar Square, London, W.C.2. It will be seen that the programme falls into three divisions. Division 1 will contain single reports, from each national committee, to include: (*a*) a survey of the energy resources of the country; (*b*) a historical record of the development of the resources of the country and of prime movers for utilizing them, covering the period since the First World Power Conference in 1924. Division 2 will consist of individual papers, dealing comprehensively with the preparation of fuel of every kind. Division 3, which is perhaps the most important, is headed "Production of Power". In addition to the traditional sources of power, papers will be included on gas turbines, jet engines, hot-air engines, tidal power, wind power, solar energy, terrestrial heat, thermal energy derived from the sea, and atomic energy. It is hoped that, despite the manifold difficulties surrounding the preparation of papers on atomic energy, some valuable contributions will be forthcoming. Although the technical programme does not contain a separate division on utilization, the hope is expressed that papers will be presented dealing with the design and relative advantages of different types of prime movers for specific purposes, for example, aviation, land transport and marine propulsion. Unesco has recently made a grant towards the statistical work carried out by the World Power Conference.

Arctic Ice

THE publication of the *Year-Book of the State of the Ice in the Arctic Sea* issued by the Danske Meteorologiske Institut, which was suspended in 1940, has been resumed on the traditional lines with charts for the spring and summer months. The Institute is trying to collect material for the years 1940–45 to make possible the publication of a report for that time. The present issue is for 1946. In that year the Barents Sea had rather less ice than usual. Details from the Kara Sea are lacking. Spitsbergen was open on the west for most of the summer, and in the north for longer than usual; but in the east, including Storfjord, there was continuous pack-ice until late in

August. In the Greenland Sea ice was less than usual, and parts of the coast of Greenland had periods of accessibility. Twice during May the East Greenland pack touched the north-west coast of Iceland. In Davis Strait the amount of ice was rather less than usual; but its late culmination was an unusual feature. There seems to be no data available for Bering Strait and the Beaufort Sea. In the North Atlantic there was an abnormally easterly distribution of icebergs; very few bergs followed the less important western branch of the Labrador current that flows along the Avalon Peninsula of Newfoundland. But the total amount of ice in the Newfoundland area was about the usual.

Fair Isle Bird Observatory

LYING directly between Orkney and Shetland, Fair Isle has been well known as a bird migration station since Dr. Eagle Clark began his observations there in 1905. Since the Second World War, and largely through the efforts of George Waterston, Ian Pitman and Arthur Duncan, the Fair Isle Bird Observatory Trust has been formed in order to develop the use of the island as one of Europe's premier bird observatories. Already a full-time director has been appointed and a certain amount of equipment installed; but much more support will be needed before the natural ornithological advantages of the island can be investigated. Copies of an attractive booklet describing the Fair Isle Bird Observatory can be obtained from 48 Castle Street, Edinburgh.

Kangaroos

THE ordinary person probably regards the kangaroo as the most characteristic of the native animals of Australia, and the Macropodidæ is the family with the largest number of species and contains the largest animals. Considerable work has been done on this group; but nevertheless the review of the family given by G. H. H. Tate (*Bull. Amer. Mus. Nat. Hist.*, 91; 1948) is timely. The review falls into two parts, one on the anatomy and phylogeny, and the other on the taxonomy. It is suggested that phylogenetically two basal stocks, the subfamilies Potoroinæ and Macropodinæ, can be recognized; but the relationship between them is not clear. Some authorities have gone so far as to suggest that each has arisen independently from a phalangeroid stock. It seems clear that no division of the recent phalangerids could have given rise to either subfamily. Within the groups the author gives reasonable phylogenetic lines. To the four generally recognized subfamilies, the author adds a fifth for the reception of certain extinct species, the Palorchestinæ. He recognizes and defines 107 distinct forms falling into 22 genera. A considerable literature has grown up around the question of the specific identification of the kangaroo recorded by Captain Cook, and, after a review of this and other evidence, the author concludes that the animal in question is *Macropus canguru canguru*, a north-eastern subspecies, the south-eastern equivalent of which is *Macropus canguru major*.

Radar Training Devices

AT a meeting of the radio section of the Institution of Electrical Engineers on November 2, Mr. G. W. A. Dummer presented a paper entitled "Aids to Training —The Design of Radar Synthetic Training Devices for the R.A.F.". In this paper, the author describes how, during the War, work was conducted by the Trainer Design Group at the Telecommunications Research Establishment, in the development of equipment used by the Royal Air Force for training operators, navigators and controllers in radar techniques. With the introduction of each new radar system, a simple synthetic trainer was designed concurrently. As operational experience was gained on the equipment, a more complex crew trainer was developed; this provided accurate presentation of a moving synthetic target or targets, and complete operational practice with a record of the trainee's errors. Approximately seventy different types of trainers were developed for the various radar systems, varying in scope from the provision of simple synthetic echoes to a complex device such as the reproduction on the ground of a complete night-fighter interception in the air. The fundamental principles necessary for the control of synthetic targets in two and three dimensions are discussed in the paper, the presentation of which was illustrated by an extended cinematograph film. With the end of the War the urgent necessity for training devices declined, and comparatively few trainers are being designed at the present time. In the discussion at the meeting, however, various speakers pointed out the need of this type of equipment for training the crews and operators of civil aviation services.

Distance of Canopus

MR. O. R. WALKEY has investigated the distance of Canopus (α Carinæ) by a new line of approach (*J. Brit. Ast. Assoc.*, 58, No. 6; 1948). The results obtained for this star vary considerably, some of the derived parallaxes being more than five times those of others. Mr. Walkey approaches the problem from the secular parallax of the star, a star's proper motion being frequently a fair criterion of its distance, and the radial velocity of Canopus provides a clue in the present case. Accepting results he has obtained for the apex of the solar motion (*Mon. Not. Roy. Ast. Soc.*, 106, No. 4; 1946) and also for the velocity of the sun, the antapex of this motion, R.A. 90·2°, Dec. −28·7°, is just 24° north of Canopus, and as the recessional radial velocity of the star is 20·8 km./sec., we may regard it as stationary within the velocity framework. The proper motion of Canopus in R.A. is given as $0{\cdot}0020^{s} \pm 0{\cdot}0012^{s}$ in G.C., and the large probable error in R.A. should, Mr. Walkey thinks, warrant the simplicity of considering the motion in declination alone in the investigation. This is 0·017″ + 0·0015″ towards the solar antapex, and applying the correction for galactic rotation it becomes 0·0126″ ± 0·0015″. If this represents the crosswise reflex of the sun's motion from the antapex, the absolute parallax of Canopus is 0·0071″ ± 0·00009″. Adopting a final parallax of 0·007″ or a distance of 450 light-years, the absolute magnitude of the star is −6·6. It is significant that this distance finds confirmation in Charlier's determination of the distance of the centre of the brighter *B*-type stars lying in Carina (*Medd. Lund.*, Series ii, 14; 1916. 34; 1926). The revised and higher luminosity basis, of one magnitude brighter than that used by Charlier for the given *B* stars, places their centre at a distance represented by a parallax of 0·0072″.

International Union of Biological Sciences

THE programme of symposia, organised with the help of Unesco by the International Union of Biological Sciences, started in November 1947 with a symposium on trace elements in plant physiology, held at Rothamsted (see *Nature*, **161**, 364; 1948). The report of this Conference is in the press at Chronica Botanica Co., Waltham, Mass. The second symposium of this series was held during June 14–19, 1948, at Utrecht; it dealt with the theoretical basis of botanical nomenclature and systematics. The full report will also be published by the Chronica Botanica Co. A third symposium was the first International Congress on the Physio-Pathology of Animal Reproduction at Milan; it lasted two days (June 21–22, 1948) and its theme was: "Interactions between Eggs and Sperm". The full report is to be published by its secretary, Prof. T. Bonadonna, Via Fratelli Bronzetti 17, Milan. A symposium on Terminology of Cytogenetics and Genetics was held at Stockholm during July 15–16, 1948. This symposium carried further the work done at the pre-war symposium held in London during August 14–15, 1939. A committee has been formed to supervise the preparation of the full report, which probably will be published as a separate number of *Bibliographia Genetica*. Finally, a fifth symposium was held at Stockholm during August 5–7, 1948, which discussed the scientific foundations of an international organisation for combating agricultural pests. A programme for further work on the subject has been drawn up; and the report of the meeting will be published by the general secretary of the International Union, Prof. P. Vayssière, Muséum d'Histoire Naturelle, Paris.

City and Guilds of London Institute

The report of the Council of the City and Guilds of London Institute for 1947 gives ample evidence of the Institute's growing activities. There has been a large increase in the number of students at the City and Guilds College, particularly postgraduate and research students. In the Department of Technology the total number of candidates examined was 47,807, 7,336 higher than the previous highest total of 40,471 recorded in 1939. Among the regulations and syllabuses for existing examinations which have been revised during 1947 are those of petroleum and petroleum products, electrical engineering practice, road service work and motor-vehicle electrician's work; while among syllabuses at present being considered for introduction later into the examinations conducted by the technology department are courses in works administration subjects for craftsmen, servicing and maintenance for instrument mechanics, and courses for electrical apprentices in iron and steel and other heavy engineering work. Copies of the report may be obtained from Gresham College, Basinghall Street, London, E.C.2.

Exhibition of Radiographs

An exhibition of industrial radiographs will be held at the spring meeting of the Industrial Radiology Group at the Institute of Physics on February 18 and 19, 1949. Entries should be suitable for showing on standard viewing lanterns (mounted prints may also be submitted) and should, wherever possible, be accompanied by photographs or samples of the specimens which they represent. A short description should accompany each entry. Intending exhibitors should apply to the Institute of Physics, 47 Belgrave Square, London, S.W.1, for entry forms.

"Animals of Australia"

The third of the series of natural history booklets has now been published by the Glasgow Art Galleries and Museum. Like the first two of the series, "Animals of Africa" and "Animals of India", the new booklet has been written primarily as an account of the Australian habitat group, one of the large groups in the Mammal Court of the Museum. The booklet contains a simple description of the life and habits of each of the animals as well as a photograph and outline drawing which serves as a key to the display.

Announcements

The president of the Royal Society has appointed the following vice-presidents for the ensuing year: Sir Thomas Merton, treasurer of the Royal Society; Sir Edward Salisbury, biological secretary of the Royal Society, director of the Royal Botanic Gardens, Kew; Sir James Chadwick, master of Gonville and Caius College, Cambridge; Prof. A. C. Hardy, Linacre professor of zoology in the University of Oxford.

Dr. H. Greinacher, professor of experimental physics in the Faculty of Sciences of the University of Berne, has been awarded the Theodor Kocher Prize by the University in recognition of his skill in experimental work, specially for the development of the 'Greinacher circuit', widely used in applied X-rays. This circuit, which was described in 1914 (*Deutsch. Phys. Gesell. Verh.*, **16**, 320; April 15, 1914), is one of the best-known circuits that combine voltage-multiplying with a constant potential.

Dr. F. A. Burchardt, of Magdalen College, has been appointed director of the Oxford University Institute of Statistics, with effect from January 1, in succession to Mr. D. G. Champernowne, now professor of statistics in the University.

Mr. A. W. Hendry has been appointed to the University readership in civil engineering tenable at King's College, University of London, as from May 1, 1949. The title of professor of chemical pathology in the University has been conferred on Dr. Jocelyn Patterson, in respect of the post held by him at Charing Cross Hospital Medical School. The degree of D.Sc. has been conferred on Mr. E. R. Leonard, an internal student.

The Langley Memorial Prize, offered by the London School of Hygiene and Tropical Medicine, and open to competition among officers, past and present, of the West African medical departments, has been awarded to Dr. D. Fitzgerald Moore for an essay entitled "Nutritional Eye Disease and Effects of Nutritional Retrobulbar Neuritis".

Trinity College, Cambridge, offers research studentships and Dominion and Colonial exhibitions every year; the next elections will take place in July 1949. Research studentships are open to graduates of universities other than Cambridge who are not more than twenty-six years of age, although in computing his age a candidate may deduct any period of war service. The exhibitions are open to undergraduates as well as those wishing to undertake research. Applications, to be sent through the head of the candidate's university, must reach the Senior Tutor, Trinity College, Cambridge, not later than May 1, 1949.

Two Christmas Lectures, for older children, will be delivered at the Institution of Electrical Engineers by Dr. P. Dunsheath, under the general title "Electricity: a Giant Harnessed". The Lectures will be given on December 29 and 30 at 3 p.m.

X-Ray Line Broadening in Cold-worked Metals

It is known that X-ray line broadening in cold-worked metals appears to tend towards a limiting value as the amount of deformation increases. A possible cause of this might be self-annealing. If, as is very probable, line broadening is due mainly to internal strains, self-annealing would lead to strain release or recrystallization as soon as the internal strains reach a critical magnitude, which, of course, would depend on the temperature.

Since self-annealing must be insignificant at the temperature of liquid nitrogen, the limit to the line broadening ought to be very much higher or absent in metals cold-worked at this temperature if it is due to thermal recovery or recrystallization. In this case, moreover, the increased line breadth observed after deformation and subsequent X-ray exposure at a low temperature would fall to the room-temperature value after keeping the specimen at room temperature for the time needed for an X-ray exposure.

In order to test whether line broadening is influenced in this way by self-annealing, we have taken back-reflexion X-ray photographs from wire specimens plastically deformed in torsion. The progress of the broadening of the (311) line with deformation is shown in Fig. 1 for high-conductivity copper. The low-temperature results were obtained by deforming and exposing the specimens while liquid nitrogen was flowing over them. Further measurements after warming up to room temperature have shown that no appreciable recovery occurs within several weeks.

For commercially pure aluminium deformed at either temperature (Fig. 2), the line breadth decreases slowly on keeping the specimen at room temperature; however, the recovery of the line breadth is still incomplete after several weeks.

The absence of a significant decrease of the line breadth within the time needed for the deformation of the specimen and the subsequent X-ray exposure shows that the limit to the line broadening cannot be due to recovery or recrystallization. With metals that show rapid recovery of mechanical and other properties at room temperature, of course, recovery may limit the line breadth to lower values than would be attained in its absence. Thus, Hutchison[1] has recently found that the line broadening observed with high-purity aluminium deformed and exposed at the temperature of liquid air disappears when the specimen is brought to room temperature. This is in accord with the fact that high-purity aluminium is self-annealing and even recrystallizes rapidly at room temperature.

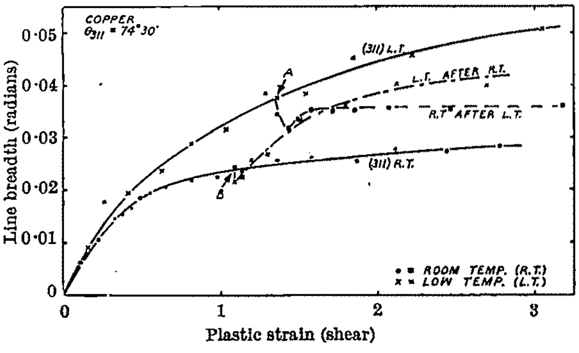

Fig. 1

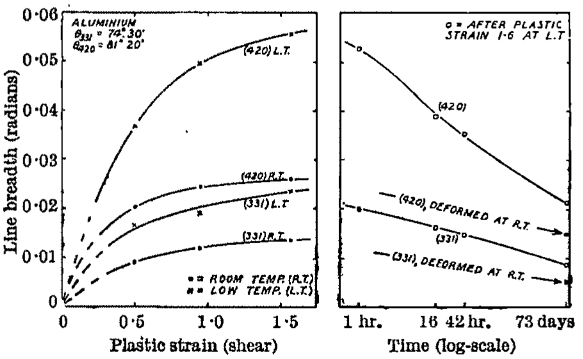

Fig. 2

Our observations support the view put forward by van Arkel and others[2,3] that line broadening, being due to internal stresses, is limited by the circumstance that the shear stress cannot rise beyond the yield stress of the material (which depends on the preceding plastic strain). Obviously, the hydrostatic component, and, therefore, the total value of the microscopic local stresses, cannot be of a higher order of magnitude than the local shear stresses. Figs. 1 and 2 show that, within the strain-range studied, the line breadth does not definitely converge towards a constant value; the line breadth curves merely become flatter with increasing strain, as yield stress-strain curves do.

It seems surprising that the stresses responsible for the line broadening are of the order of the macroscopic yield stress, whereas the 'theoretical shear strength' and the stresses around the dislocations must be of a higher order of magnitude. The answer seems to be that stresses of the order of the 'theoretical shear strength' never occur, except in the centre zone of dislocations; new dislocations arise from existing ones by some multiplication mechanism[4,5] (for example, by the glide process jumping from one glide plane to another). The dislocations, however, cannot contribute much to a Debye–Scherrer ring, for several reasons. First, the total volume of the highly stressed regions around the dislocations is small compared with the volume of the specimen; then, the range of strains around the dislocation is so large that the corresponding strain broadening extends over a very large angle; and, finally, there must exist an extreme small-size broadening, since the size of the coherently diffracting regions in a dislocation cannot amount to more than a few interatomic spacings. The high stresses around the dislocations, therefore, contribute mainly to the background in the X-ray photographs, while the line broadening is due to stresses of the order of the macroscopic yield stress. If other factors contributing to the background (impurities, thermal movement) can be eliminated, the density of the background may give a measure of the density of dislocations in the material.

Photo-elastic stress measurements in plastically deformed transparent crystals[6,7] also show that most of the volume (the glide packets) is not stressed beyond the macroscopic yield value; the volume occupied by the thin glide zones (between the glide packets), where the high stresses are concentrated, is very small.

The close connexion between line broadening and yield stress is shown by experiments in which the temperature was changed during the deformation. In Fig. 1, the broken curve resulted from deformation at room temperature, after the specimen had been strained up to point A in liquid nitrogen. After a small initial dip, the curve of the line breadth tends with increasing strain towards that for a specimen deformed entirely at room temperature. Similarly, the line-breadth curve of a specimen strained to the point B at room temperature, and from then on in liquid nitrogen, tends towards the curve for deformation in liquid nitrogen from the beginning. After a change of temperature, the line breadth tends towards the values characteristic of the new temperature, in general, only if additional deformation is carried out, but not spontaneously in the course of time (unless the material shows general effects of self-annealing). The same behaviour was observed by J. Los[8] for the yield stress of copper and aluminium deformed alternately at low, and at room, temperature.

Recording of Charged Particles of Minimum Ionizing Power in Photographic Emulsions

SINCE the announcement of a photographic emulsion of sufficient sensitivity to record unmistakably the tracks of electrons[1], interest has centred on the possibility of achieving further increases in sensitivity, the recording of the complete tracks of *any* charged particle being the ultimate aim[2,3].

A singly charged particle, with a velocity of the order of 90 per cent of that of light, has the lowest ionizing power that a charged particle can possess. The energy of an electron, when it possesses this minimum ionizing power, is between 500 and 1,000 keV., and the residual path-length in the emulsion of such an electron will be between 800 and 2,000 μ, assuming a stopping power to electrons of 2,000 for the emulsion. The present commercially-available electron-sensitive plates (Kodak *NT2a*) will record tracks of electrons with energies of up to 80 keV., the residual path-length[4], in the emulsion, of an electron of 80 keV. being about 30 μ. Since the ionizing power of such an electron is approximately three times that of the minimum, an emulsion with a threefold increase in sensitivity over that of *NT2a* is required in order that tracks of particles of minimum ionizing power should be recorded.

The experiments which are being made in these Laboratories already show that such substantial increases in speed over that of the *NT2a* emulsion are possible that we are encouraged to believe that sensitivity to minimum ionizing power can be attained. The accompanying photomicrographs were obtained from γ-ray experiments on 200-μ thick coatings of an experimental emulsion. They show tracks never before realized, and their great interest is regarded as sufficient to justify their description at this early stage in the evolution of such emulsions.

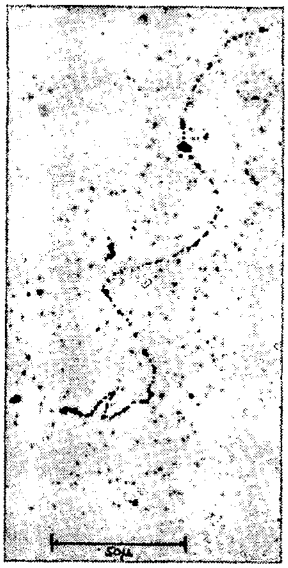

Fig. 1

Owing to the high scattering which electrons undergo in the photographic emulsion, particularly towards the end of their range, complete tracks ending in the emulsion, with a length of the order of 1,000 μ, will be very rare. A further difficulty in obtaining a complete recording in the emulsion of high-energy electron tracks is that the production of secondary electron tracks is very frequent, and, again due to the high scattering of electrons, the chance that all the secondary electron tracks will end in the emulsion is very small.

Thus, although a 1,000-μ track of an electron which comes to rest in the emulsion would be the more conclusive evidence that the minimum ionizing power could be recorded, such a track has not yet been

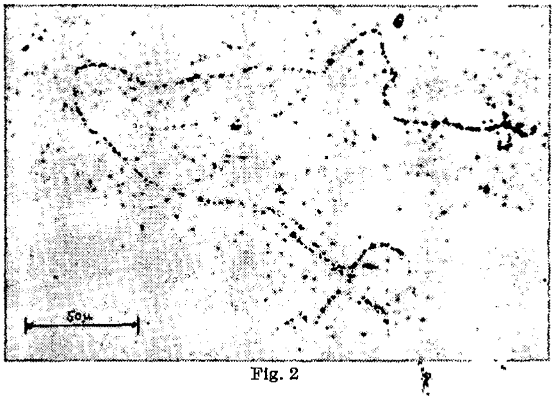

Fig. 2

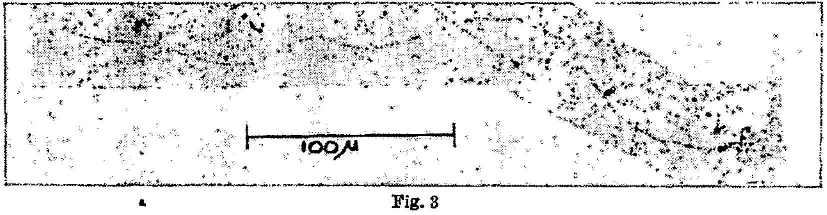

Fig. 3

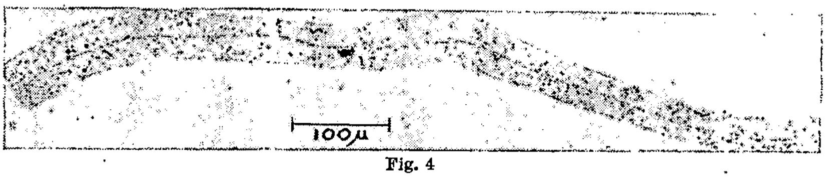

Fig. 4

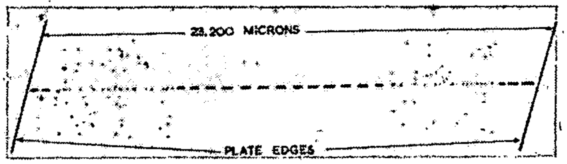

Fig. 5

found, and the accompanying selection of photomicrographs has therefore been chosen to demonstrate the sensitivity of this emulsion.

Fig. 1 is a photomicrograph of an electron track 240 μ long which ends in the emulsion, and was selected because no secondaries are formed and the scattering perpendicular to the emulsion plane is small. Fig. 2 is a photomicrograph of an electron track 350 μ long which has secondaries at the low-energy end, but otherwise is singularly free from such tracks. There is a confused bunch near the beginning of this track; but there is some doubt as to whether all these tracks are associated with that of 350 μ or not. The capability of the emulsion to record a complete electron track of 350 μ is, however, amply demonstrated. Fig. 3 is a photomicrograph of an electron track 400 μ long, which probably ends in the emulsion with the formation of at least one secondary, and which shows appreciable scattering throughout the whole of its recorded range. Fig. 4 is a photomicrograph of a track, very probably made by an electron, which is 830 μ in length, and shows some scattering throughout the whole of its recorded path. It does not end in the emulsion. Fig. 5 is a photomicrograph of a track which passes completely through the emulsion from one edge of the plate to the other. This track is perfectly straight, has a total length in the emulsion of 23,200 μ, and a constant grain-density throughout the whole of this length. Although the possibility cannot be ruled out that the particle producing this track was not an electron, such tracks have frequently been found in emulsions of this sensitivity after exposure to gamma rays, whereas the corresponding unexposed control has been free of them. In general, the tracks are shorter than those recorded here, as the chance that the particle makes such a small angle with the plane of the emulsion that it remains in the emulsion from one side of the plate to the other is very small; but similar tracks of 5,000 and 10,000 μ have been observed.

It is considered that these photomicrographs provide very strong evidence that an emulsion capable of recording the tracks of charged particles of any energy has been produced.

I wish to express my gratitude to Dr. D. T. King, of the H. H. Wills Physical Laboratory at Bristol, for selecting the tracks shown in Figs. 1, 2 and 5, and for helpful discussions on their interpretation; also to Miss P. Dyer of the same Laboratory for preparing the photomicrographs and mosaics for these figures, and to Mr. Cooke of the Kodak Laboratories for preparing the photomicrographs and mosaics for Figs. 3 and 4. This letter is based on work carried out under contract to the Atomic Energy Research Establishment, Ministry of Supply, whose permission to publish is gratefully acknowledged.

Absorption and Dispersion of Ultrasonic Waves in Acetic Acid

IN a recent communication, Pinkerton[1] has shown that for frequencies less than 70 Mc./sec. the absorption of ultrasonic waves in acetic acid can be attributed to a relaxation mechanism arising from the perturbation of a molecular equilibrium by the ultrasonic vibrations. His measurements were carried out in the frequency range 7·5–67 Mc./sec. and confirmed the earlier results by Bazulin[2].

Pinkerton concludes that, in accordance with the theoretical work of Kneser[3], the pressure absorption coefficient, α, for a frequency of excitation $f (= \omega/2\pi)$, can be described in terms of the relaxation time, τ $(= 1/2\pi f_m)$, by the equation

$$\begin{aligned}\alpha/f^2 &= \frac{\alpha_1}{f^2} + \frac{A}{1+\omega^2\tau^2}, \\ &= \frac{\alpha_1}{f^2} + \frac{A}{1+(f/f_m)^2}\end{aligned} \tag{1}$$

where the component α_1/f^2 ($= 155 \times 10^{-17}$ sec.^{2} cm.$^{-1}$ for a temperature of 17·5° C.) represents the absorption due to viscosity, heat conduction, and any further possible relaxation process occurring above 100 Mc./sec. (Strictly, A can only be treated as a constant if the velocity dispersion is small, as is here the case (Fig. 3).) Equation (1) can be rewritten

$$(\alpha/f^2 - \alpha_1/f^2) = \frac{\alpha'}{f^2} = \frac{A}{1+(f/f_m)^2}, \tag{2}$$

where α' represents the contribution to the absorption due to the relaxation mechanism under investigation. If v is the velocity of propagation, the quantity

$$\mu = \alpha'\lambda = \frac{Avf}{1+(f/f_m)^2} \tag{3}$$

attains a maximum value at the frequency

$$f = f_m = \frac{1}{2\pi\tau}. \tag{4}$$

Pinkerton estimates that, for a temperature of 17·5° C., f_m should be around 2×10^6 c./s. This is, however, below the lowest frequency employed in

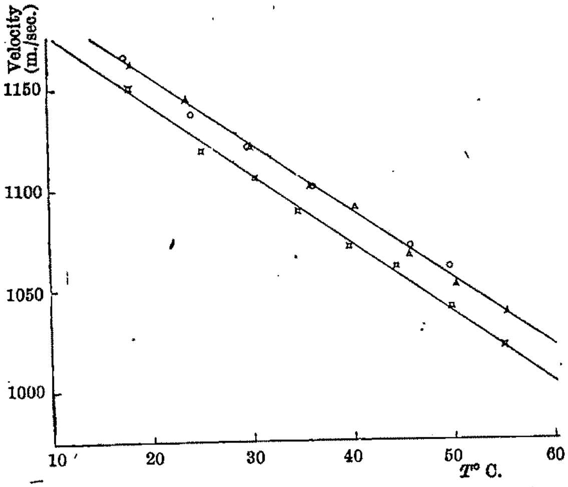
Fig. 2. Calculated curve showing the variation of $\mu = \alpha'\lambda$ with frequency at 17·5° C.



⊙—⊙—, 5 Mc./sec.; △—△—, 4 Mc./sec.; □—□—, 0·5 Mc./sec.

Fig. 3. Velocity dispersion in acetic acid

his experiments, and we have now extended the measurements to obtain values for the absorption in the frequency range 0·5–9·8 Mc./sec.

A pulse technique has been used[4,5,6] which enables the velocity of propagation to be measured[7] in addition to the absorption coefficient. From equations (2) and (3)

$$\frac{1}{\alpha'} = \frac{1}{A}\left[\frac{1}{f^2} + \frac{1}{f_m^{\,2}}\right]. \qquad (5)$$

The value of A and a first estimate of f_m can therefore be derived from a plot of $1/\alpha'$ against $1/f^2$. A more reliable estimate of f_m can be calculated from the slope of the line obtained by plotting $\sqrt{A/\frac{\alpha'}{f^2} - 1}$ against frequency. The values are as follows:

$T°$ C.	$\frac{a_1}{f^2} = \left[\frac{a}{f^2}\right]_{f \gg f_m}$ sec.^{2} cm.$^{-1}$	$A = \left[\frac{\alpha'}{f^2}\right]_{f \ll f_m}$ sec.^{2} cm.$^{-1}$	Frequency for maximum μ	
			1st estimate	2nd estimate
17·5	155×10^{-17}	$175{,}000 \times 10^{-17}$	$0{\cdot}500 \times 10^6$ c./s.	$0{\cdot}501(2) \times 10^6$ c./s.

The curves of Figs. 1 and 2 have been obtained by substituting these values in equations (2) and (3) respectively, and it will be seen that there is good agreement between the experimental points and the calculated curves.

Corresponding to the maximum in μ, a dispersion of the velocity has been recorded, as shown in Fig. 3. The values of the velocity above 4 Mc./sec. were all found to coincide with the upper line, whereas the lower line gives the results at the lowest frequency of measurement; the values for the intervening frequency-range lie between these two extremes. The maximum change in velocity to be expected from Kneser's theoretical calculations is given by

$$\frac{\Delta v}{v} \approx \frac{\mu_{\max}}{\pi} \approx 1{\cdot}6 \text{ per cent at } 17{\cdot}5° \text{ C.}$$

The value obtained is slightly less than this, the discrepancy being attributed to the limited accuracy of the velocity measurement.

Spakowski[8] has previously reported a velocity dispersion in acetic acid; but his values are about 10 per cent greater than the present measurements indicate.

The temperature dependence of f_m and $\mu_{\max}$ has been studied in conjunction with Pinkerton, and it is hoped to publish these results at a later date. We wish to thank Mr. Pinkerton for having provided his experimental values for inclusion in Figs. 1 and 2.

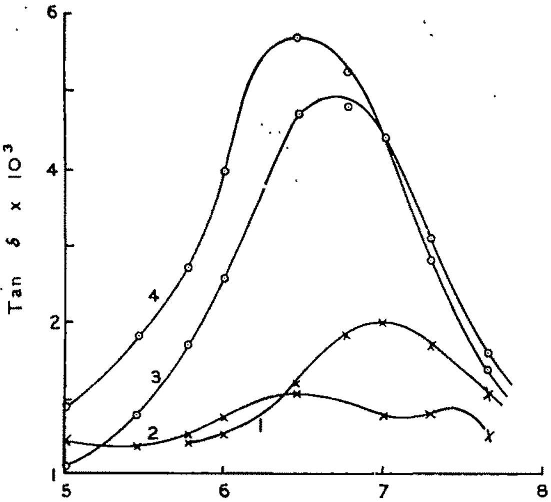
Dielectric Relaxation-Times of Solid Solutions of Aliphatic Long-Chain Esters and Ketones in Paraffin Wax and *n*-Hexacosane

In the search for relationships between electrical properties and the chemical and physical structures of solid dielectrics, the experimental investigations by Jackson[1], Sillars[2] and Pelmore[3] are of considerable interest. These workers incorporated small quantities of aliphatic long-chain esters in paraffin wax and measured the dielectric loss (tan δ) of the resulting mixtures over a range of frequencies, the inverse of the angular frequency (ω) for the maximum tan δ giving the relaxation time (τ) of the ester molecules. This work was extended by Fröhlich[4] in a theoretical study of a model comprising a crystalline paraffin hydrocarbon in which a small proportion of the molecules was assumed to be replaced by molecules of a polar compound, such as a ketone or ester, of a shorter chain-length. The transition of the polar molecules from one position of the equilibrium to another having opposite dipole direction required the crossing of an energy barrier which increased in proportion to the chain-length. This led to an equation for the relationship between the relaxation time and chain-length, in which some of the constants were determined from the experimental results referred to above.

As paraffin wax is not a simple crystalline structure, it was thought desirable to conduct experiments using a pure hydrocarbon as the non-polar medium. An investigation is therefore being made in this laboratory of the relaxation times of various polar compounds in both paraffin wax and *n*-hexacosane



Dielectric loss curves for 0·1-m. solutions of: (1), decyl laurate in paraffin wax; (2), decyl laurate in n-hexacosane; (3), laurone in paraffin wax; (4), laurone in n-hexacosane

($C_{26}H_{54}$). The results for the ketone, laurone ($C_{23}H_{46}O$), and an ester of similar chain-length, decyl laurate ($C_{22}H_{44}O_2$), are shown graphically in the accompanying figure. The curve for decyl laurate in paraffin wax is of the type obtained by Jackson[1] and Sillars[2] with the ester, cetyl palmitate. The corresponding n-hexacosane system, however, gave an unsymmetrical curve showing no definite relaxation-times. This difference in dielectric behaviour is probably associated with the presence or absence of amorphous regions in the two solvents, since this is the chief difference in their physical structures. The paraffin wax – decyl laurate system would thus be a solution in which the molecules of the latter fit loosely into amorphous regions in the solvent, whereas the n-hexacosane mixture may not be a true solution but a eutectic consisting of n-hexacosane interspersed with aggregates of ester molecules.

In contrast to the esters, the ketone, laurone, gave a normal-shaped curve in n-hexacosane, and hence it is likely that this system is a true solid solution, of the type postulated by Fröhlich, in which the polar molecules enter the crystal structure by replacing hydrocarbon molecules. In the paraffin wax medium, also, the laurone molecules probably occupy crystalline positions, since the maximum frequency value is lower than for the ester of similar chain-length, indicating a higher energy-barrier between the two equilibrium positions of the molecules. The results discussed above were in agreement with the data obtained from measurements with other esters of the C_{22} series, and also with the ketone, myristone ($C_{27}H_{54}O$), and esters of similar chain-length.

From these results it seems that Fröhlich's model applies exactly to solid solutions of the type formed by ketones in a pure hydrocarbon. In determining the constants in the relationship between relaxation-time and chain-length, however, reference was made to the experimental evidence from the solutions of the 'amorphous centre type' formed by esters in paraffin wax. Although their behaviour is similar to that of the ketone solutions, the application of the relationship to the latter would require modification of the constants involving the energy barriers between equilibrium positions of the polar molecules.

The measurements of tan δ were made with a Q-meter, using a sample-holder similar to that described by Hartshorn and Ward[5]. During measurement the temperature was 22° C. (± 0·5° C.).

More complete results of this programme will be published elsewhere.

Variation of Standard Electrode Potentials with Temperature

GILBERT[1] has recently directed attention to the desirability in corrosion studies of being able to compare directly potentials measured at different temperatures.

The standard electrode potential of the silver/silver chloride electrode has been measured over a temperature range 0–60° C. by Harned and Ehlers[2], and they have shown that their results obey the empirical equation:

$$E^\circ_{(T)} = b + c(T - 298) + d(T - 298)^2 + f(T - 298)^3,$$

T being the absolute temperature, and b, c, d and f constants the values of which have been determined.

The value of E° at any temperature calculated from this equation represents, however, only the value of this potential balanced against the standard potential of the hydrogen electrode *at the same temperature*;

that is, $$\underset{(T)}{E^\circ} = \underset{(T)}{E^\circ_{Ag/AgCl}} - \underset{(T)}{E^\circ_{H}}.$$

In order to make any absolute comparison, it is necessary either (*a*) to calculate or determine experimentally the absolute change of E°_H with temperature, or (*b*) to assume this change to be zero. Gilbert has pointed out the difficulties of determining this change experimentally, and has asked whether assumption (*b*) may be made.

The following argument based on an analysis of the processes which take place in a cell of the type shown below would appear to make it clear that the potential of the standard hydrogen electrode (as that of any other electrode) does vary with temperature. (A cell rather than an individual electrode has been considered because of the doubt that exists in the conception of the absolute potential of a single electrode.)

Consider the cell

$$\begin{array}{c|c:c|c}
\multicolumn{1}{r}{-} & & & \multicolumn{1}{l}{+} \\
H_2 & H^+ \ (a = 1) & H^+ \ (a = 1) & H_2 \\
1 \text{ atm.} & \text{Temp. } T_1 & \text{Temp. } T_2 & 1 \text{ atm.} \\
\multicolumn{1}{r}{E_1} & & & \multicolumn{1}{l}{E_2} \\
 & \text{I} & \text{II} &
\end{array}$$

Assume that current flows in the outside circuit from the electrode at T_2 to that at T_1, and that all thermo-electric effects in the leads and the effect of the liquid junction potential have been eliminated. At electrode I, hydrogen passes into solution as hydrogen ions, and at electrode II the reverse process occurs.

The E.M.F. of the cell may be expressed as follows:

$$E = \frac{1}{F}\left\{[\tfrac{1}{2}(D_{\mathrm{H}_2})_{T_1} + \tfrac{1}{2}T_1\,\Delta S_1 - NeI - (W_{\mathrm{H}+})_{T_1}] - [\tfrac{1}{2}(D_{\mathrm{H}_2})_{T_2} + \tfrac{1}{2}T_2\,\Delta S_2 - NeI - (W_{\mathrm{H}+})_{T_2}]\right\},$$

where D_{H_2} is the heat of dissociation of hydrogen, that is, decrease in heat content, and ΔS the corresponding entropy change at the temperature shown; I represents the ionization potential of hydrogen, and $W_{\mathrm{H}+}$ the free energy of solvation of 1 gm.-ion hydrogen ions at the temperature subscribed. In so far as the constituent parts of the E.M.F. may be considered as belonging to the two electrodes individually, the potential of the hydrogen electrode at temperature T_1 is represented by the terms in the first square bracket, and that of the hydrogen electrode at temperature T_2 by the terms in the second.

The free energy terms considered above are unquestionably functions of temperature, and it follows, therefore, that the potential of the hydrogen electrode changes with temperature.

The above analysis of the electrode process, which is essentially that used by various authors including Butler[3], neglects, of course, all thermo-electric effects in the metal leads in the outside circuit and the contribution to the E.M.F. of the liquid junction potential, both of which effects would, it is presumed, be considerable.

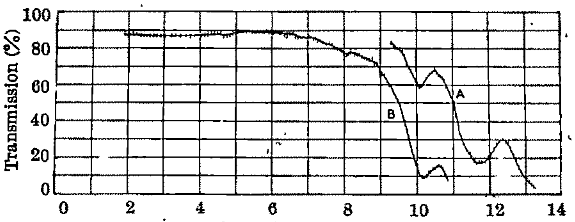
Absorption of Magnesium Oxide in the Infra-Red Region

In 1935 Barnes, Brattain and Seitz[1], investigating the absorption of magnesium oxide in the infra-red, reported some forty or so fine absorption lines in the range from 6 μ to 15·6 μ. In 1934 Fock[2], using fumed magnesium oxide, had reported the eigen-frequency to be at 17·3 μ, with subsidiary maxima at 14·8 μ, 6·8 μ and 25 μ, but no fine structure. Such a fine structure was hitherto unknown for face-centred cubic crystals, though it has been reported for quartz[3] and calcite[4]. The theory advanced by these authors to explain the fine structure is based on the interaction of crystal vibrations as originally suggested by Born and Blackman[5]; but the assumptions which lead to the details of the fine structure do not appear to be correct[6].

This fine structure does not seem to be consistent with any form of lattice theory of infra-red absorption, and a further investigation, therefore, appears to have both theoretical and practical interest.

The curves reproduced here are typical results in the range up to 14 μ for specimens of different thickness. Values of the percentage transmission of cleaved specimens of artificially grown magnesium oxide, obtained from the same firm which supplied Barnes, Brattain and Seitz, were taken at a mean separation of 0·07 μ, using a large rock-salt prism spectrometer. Each point is the mean of two results obtained from two separate runs through the spectrum, and in no case did the values at any one wave-length differ by more than 2 per cent. Each result in each run is the mean of three results taken consecutively. Experiments showed that by using a Welsbach mantle as the source of radiation, the scattering within the apparatus is negligible; but that with a Nernst filament as a source some five to ten per cent of the radiation at 11 μ was due to scattering from the high-energy peak in the spectrum of the Nernst filament.



Curve *A*, specimen 0·075 mm. thick; curve *B*, specimen 0·467 mm. thick. Slit-width covers a band of approx. 0·1 μ. Vertical lines indicate probable error

It will be seen that the fine structure reported by Barnes, Brattain and Seitz has not been confirmed. Two distinct subsidiary maxima have been found, one at 10·10 μ and the other at 11·7 μ.

The curves for various thicknesses are consistent with each other, that is, they all give the same value for the extinction coefficient at any one given wave-length. This is not the case in the results of Barnes, Brattain and Seitz, where the detailed shape of the absorption spectrum differs considerably for specimens of different thickness. Further, the curve for a specimen of 75 μ thickness (curve *A*) shows that it becomes practically opaque beyond 13·3 μ, while a specimen of the same thickness was found by Barnes, Brattain and Seitz to have at least 10 per cent transmission up to 15·6 μ, indicating that there must have been considerable scattering of the short wave-length radiation from their source, which was a heated platinum strip.

Preliminary results in the region from 14 μ to 25 μ show that the eigen-frequency is at 17·3 μ, as reported by Fock, with subsidiary peaks at 14·8 μ and 24·2 μ. The absorption maximum at 6·8 μ, found by Fock, has not been confirmed, and is probably due to absorbed water, as a cleaved specimen left out in the air for some weeks showed an absorption at 6·5 μ, which vanished as soon as the specimen was cleaned by rubbing with clean chamois leather.

To sum up, the fine structure observed by Barnes, Brattain and Seitz has not been confirmed. The eigen-frequency is at 17·3 μ, and there are subsidiary maxima on the short wave-length side of the eigen-frequency at 10·1 μ, 11·7 μ and 14·8 μ, and at 24·2 μ on the long wave-length side.

I should like to thank Dr. L. Kellner for suggesting the problem, supervising the practical work and giving much advice, and Dr. M. Blackman for advice and discussion.

Systematization of Certain Binary Metallic Equilibrium Diagrams

As part of an attempt to systematize the knowledge of factors which influence the form of binary equilibrium diagrams, we have examined the available data on binary systems in which no intermediate compounds are formed. This corresponds to a state of affairs where the electrochemical effect[1] is small, and if those systems characterized by a 100 per cent range of solid solubility are ignored, the systems considered fall into two distinct classes; namely, those in which a region of liquid immiscibility is encountered (Fig. 1), of which aluminium–potassium is an example, and those which are characterized by the existence of a eutectic (Fig. 2), of which bismuth–cadmium is an example.

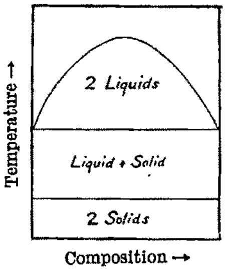

Fig. 1

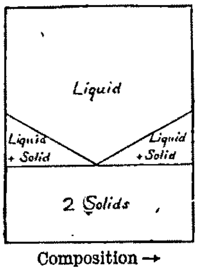

Fig. 2

Fig. 1. The aluminium–potassium type of diagram
Fig. 2. The bismuth–cadmium type of diagram

In Fig. 3 we have plotted the size factor of each system, as defined by the relation

$$\text{size factor} = \frac{L - S}{S} \times 100,$$

where L is the closest distance of approach of atoms of the larger atomic species in crystals of the pure element and S is the corresponding value for the smaller atomic species, against a 'temperature factor' $\frac{\Delta\theta}{\frac{1}{2}(\theta_1 + \theta_2)}$, where $\Delta\theta$ is the difference between the melting points of the elements and θ_1 and θ_2 are the melting point temperatures on the absolute scale.

Fig. 3 may conveniently be divided into three regions, A, B and C. In region A, where the size-factor and temperature-factor are limited by the values 30 per cent and 0·175 respectively, all systems are of a simple eutectic type (Fig. 2), in which the eutectic point is moderately near the centre of the composition scale. In region B, where the size-factor is everywhere greater than 30 per cent, we find that the two-liquid system predominates. It is, however, quite clear that although a large size-factor strongly favours the formation of a two-liquid type of diagram, size-factor is not the only controlling effect: in region C, for example, there is an approximately equal number of two-liquid and eutectic-type diagrams distributed randomly throughout the region. Moreover, in region B, the system germanium–lead is an outstanding exception to the general rule that a size-factor of more than 30 per cent is associated with a two-liquid type of diagram. This system[2] is characterized by a fairly flat liquidus curve and by having the eutectic point very near the composition of one of the pure metals; and if compared with Figs. 1 and 2, it may be regarded as being of an intermediate type.

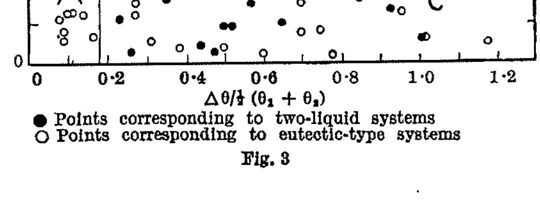

Fig. 3

In view of the existence of this intermediate type of diagram, it is of interest to examine more closely the form of the eutectic-type diagrams in region C. In this region, as the temperature-factor increases from 0·175 to 0·4, the eutectic point moves progressively away from the centre of the composition scale and the diagrams approximate to the form of that for germanium–lead. When the temperature factor is greater than 0·4, the diagrams tend to be of the intermediate type already discussed.

It has not, in the present investigation, been possible to elucidate the factors which control the formation of two-liquid or eutectic-type diagrams in region C of Fig. 3; but it is clear that within this zone a large temperature-factor tends to be associated with a eutectic diagram of the intermediate type.

Instability in Pipe Flow

WHEN considering the conditions necessary for the stability of laminar flow in a cylindrical pipe, it may be assumed that the following quantities are involved: transverse velocity gradient (dv/dx) at the point considered; distance (x) of the point from the wall; and kinematic viscosity (ν) of the liquid.

The dimensionless group arising from these quantities is

$$G = \frac{(dv)}{(dx)} \frac{x^2}{\nu} = x \cdot \frac{d}{dx} ({}_xRe) - {}_xRe,$$

where ${}_xRe$ is the localized Reynolds number $\frac{vx}{\nu}$.

In fully developed laminar flow the maximum value of G occurs when $x = d/3$, where d is diameter of pipe; and this maximum value is

$$G_{\text{max}} = \frac{8\bar{v}d}{27\nu} = \frac{8}{27}\, Re.$$

From the generalized velocity-distribution curves (for the flow near the entrance to a pipe) given by Nikuradse[1], it may be shown that the value of G_{max} increases downstream, as shown in Fig. 1, where X is downstream distance from the entrance. A value of about 2,000 is frequently assumed for the critical Reynolds number: the corresponding value of G_{max} is about 592.

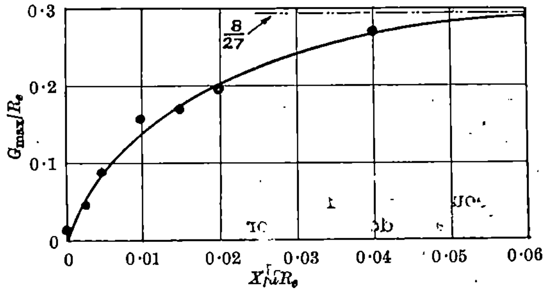

Fig. 1

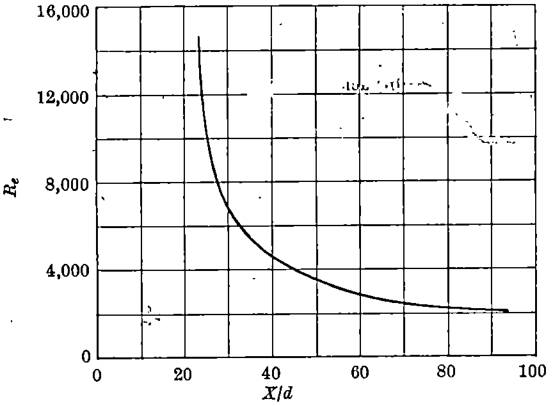

Fig. 2

Fig. 2 shows the variation of the position of the 'point of instability' ($G = 592$) as a function of Reynolds number (Re). From Fig. 2 it appears that this 'point of instability' approaches the entrance as the Reynolds number is increased.

The precise shape of the curve in Fig. 2 can, of course, only apply to flow examples in which the generalized velocity-distribution curves of Nikuradse are actually obeyed.

In Fig. 2, with flow at a constant Reynolds number, the position of the 'point of instability' is fixed. If disturbances arrive at this point, the flow should become turbulent; but if the disturbances have died away before they reach this point, laminar flow should persist. These inferences have an obvious bearing on the so-called 'higher critical' phenomena.

Fish Farming in the Belgian Congo

DR. C. F. HICKLING[1] recently gave a survey of fish farming in the Middle and Far East. He mentioned that the best results were obtained in Africa with species of *Tilapia* (Percomorphi, Cichlidæ). The study of fish-farming problems being one of the principal objects of the Fisheries Research Station at Elisabethville (Belgian Congo), it may be of interest to describe some of our observations and results.

Before trials of fish culture were made in the Belgian Congo, it was already known that some species of *Tilapia* lent themselves more or less to pond-culture. Local species were used in different parts of Central Africa: *Tilapia nigra* Gthr. in Kenya[2] and *Tilapia kafuensis* Blgr. in Northern Rhodesia[3]. In the Union of South Africa, trials were made with *Tilapia mossambica* Peters, *Tilapia Sparmani* A. Smith, *Tilapia nigra* Gthr., *Haplochromis moffati* Cast., and *Serranochromis thumbergii* Cast.[4]. The results published concern mostly the growth and the biology of these fish. Data about production are rather scarce. At the Station of Chilanga (North. Rhod.) a pond stocked with *Tilapia kafuensis* Blgr., where the fish were intensively fed, gave a production equivalent to 1,200 lb. per acre per annum (1,342 kgm. per hectare per annum).

Since 1943, trials with indigenous species of fishes of the Congo Basin have been undertaken in different parts of the country, especially in Elisabethville. Those scattered trials, by private enterprises, proved that some species of Cichlidæ are growing and breeding well in ponds. Unfortunately, the experiments were made with mixtures of different species.

The Mission Piscicole du Katanga (1946–47)[5] repeated the experiments, taking care to separate the species involved. Carrying on the work of the Mission Piscicole du Katanga, the Fisheries Research Station, Elisabethville, got some very interesting results.

Tilapia sparmani A. Smith and *Tilapia nigra* Gthr. (introduced previously from Kenya), although breeding in ponds, did not give satisfactory results. The best results were obtained with *Tilapia macrochir* Blgr. and *Tilapia melanopleura* Dum. We already know something about their breeding[6].

Like two good pond-fishes of the Far East, *Osphronemus olfax* Blkr. and *Ctenopharyngodon idellus* Cuv. and Val., *Tilapia melanopleura* Dum. is a plant-eater; two hundred fingerlings took no more than ten months to eliminate from a pond of 7 ares (0·17 acre) a dense vegetation of *Leersia hexandra.* The fish like also *Potamogetum, Hydrilla, Lagarosiphon,* etc., and eat very well boiled sweet potatoes, banana foliage and other greenstuff. T. Vaughan Jones[7], who last February, after a visit to our Station, took some fingerling *Tilapia melanopleura* to the Station at Chilanga, was able to confirm these observations.

Our experiments further indicate that *Tilapia melanopleura* is adaptable to different waters and withstands handling. *Tilapia macrochir* Blgr. is principally a plankton-eater. It does not eat weeds but likes the micro-organisms fixed upon it. Artificial feeding with mill waste gives excellent results.

Both species seem to have the same rate of growth (up to 250 gm. eleven months after being spawned). It is therefore not surprising that high yields can be obtained with these species. A pond of 85 ares (about 2 acres) was manured in July 1947 and 121 *Tilapia macrochir* weighing 10 kgm. put in. From March 1948 the fishes were fed with maize waste. Eleven months after the beginning of the experiment 4,000 kgm. of fish were collected, which is equivalent to 5,135 kgm. per hectare per annum (4,574 lb. per acre per annum).

It is easy to understand the economic value of these fishes in countries where food is rather scarce. They immediately transform the plankton and green plants into valuable foodstuffs. No materials of food value for man are needed for their artificial feeding. The two species, being of complementary feeding habits, are able to use a great part of all the available food in a pond. Their breeding habits are sufficiently different to avoid competition between them. Although we have already very interesting results with mixed populations, the ratio of the two species is not yet fully determined for ponds of different productivity.

It may be of interest to direct attention to the fact that *Tilapia melanopleura* Dum. is a good agent in malaria control. The fish eliminate the floating and semi-submerged vegetation, which are breeding places of the malaria-carrying *A. gambiæ* and *A. funestus*. Further, the fry eat mosquito larvæ.

All over the country the cultivation of both these *Tilapia* is growing rapidly. Nearly all the ponds and dams are stocked with fry coming from the *Tilapia*-strains of this Station. Some fingerlings have already been sent abroad.

Further details concerning the biology and the culture of these *Tilapia* will be published in the annual report of the Station.

Amino-Acids in the Hæmolymph of the Dragon-fly Nymph, *Aeschna cyanea*

ALTHOUGH it is well known that the non-protein nitrogen content of insect hæmolymph is high and that a large proportion of it is present as amino-acids, few investigations have been made as to their nature. Florkin and Duchateau[1] showed that the hæmolymph of *Dytiscus marginalis* contained small quantities of histidine and tyrosine, and reported the absence of arginine, tryptophane, phenylalanine and cystine. A more thorough analysis by Ussing[2] revealed the presence in the blood of *Melolontha vulgaris* of lysine, arginine, histidine, tyrosine, leucine, valine, tryptophane and almost certainly hydroxyproline. The latter is also present in the blood of *Oryctes nasicornis*.

We have investigated the hæmolymph of *Aeschna cyanea*, using the technique of partition chromatography on filter paper of Consden, Gordon and Martin[3].

Small quantities of blood (about 3 mm.^{3}) run on a partition chromatogram, using water-saturated phenol as solvent, gave coloured spots with ninhydrin, the R_F values of which (0·38 and 0·55) corresponded with those of glycine and alanine. With increased amounts of blood, spots corresponding in position to leucine or *iso*leucine, valine and proline were found.

To detect the presence of amino-acids occurring in smaller amounts, concentrated extracts were prepared by evaporating the blood from one larva (about 100 mm.^{3}) to dryness in a vacuum desiccator, suspending in about 15 mm.^{3} of 60 per cent alcohol, centrifuging, and using the supernatant solution. Thus the amino-acids were concentrated while the protein and most of the inorganic salts remained undissolved. The nitrogen content of the whole blood was determined by an ultra-micro-Kjeldahl method on a small sample (0·7 mm.^{3}) removed before concentration. A typical result was: total nitrogen, 529; protein nitrogen, 311; non-protein nitrogen, 218 mgm. per cent. Amino-acids identified: serine, glycine, lysine, alanine, tyrosine, valine, leucine or *iso*leucine, proline.

Since proline is easily recognized by its ninhydrin colour and because the R_F values were sometimes lower than expected, values for every spot were recalculated using the proline spot as standard (R_P value = 1·0).

The results were confirmed by running simultaneously a blood extract, and a blood extract to which was added one or more of the suspected amino-acids.

The results for a number of different animals are summarized in the accompanying table.

R_P-values at room temperature

Amino-acid	Pure amino-acid	Pure amino acid in blood	Blood extract (animal 15B)	Blood extracts: average for 16 runs
Serine	0·36	0·36	0·37	0·36
Glycine	0·45	0·44	0·44	0·44
Lysine	—	0·55	0·54	0·53
Alanine	0·63	0·64	0·65	0·65
Tyrosine	0·70	0·72	0·75	0·72
Valine	0·85	—	0·87	0·86
Leucine or *iso*leucine	0·94	—	0·94	0·93
Proline	1·00	—	1·00	1·00

From these experiments and those with untreated blood it appears that glycine, alanine, valine and leucine are present in the greatest concentration. Proline and tyrosine occur in moderate amounts and serine and lysine in small quantities.

Confirmation of these results was provided by the two-dimensional technique using phenol and collidine as solvents, except that no serine was demonstrated. Arginine and lysine are possibly present, and relatively large amounts of a substance, possibly a peptide, which runs at the same speed as alanine in phenol but somewhat slower in collidine.

Further experiments are in progress on the blood of other insects, and attempts are being made to obtain quantitative results.

Growth of *Culex molestus* under Sterile Conditions

Aedes ægypti and *Culex pipiens* are the only two mosquitoes which have hitherto been reared from egg to adult under sterile conditions. It is interesting to note that the autogenous *Culex molestus* can also be bred without difficulty on sterile media. The following media were found suitable for this purpose (all experiments were carried out at a temperature of 28° C.).

(1) Dried or fresh yeast (autoclaved) 1·2 gm. to 15 ml. distilled water to which 25 eggs of *C. molestus* were added under sterile conditions. On this medium the mosquitoes developed from eggs to adult in 10·5–13 days; but the adults were not viable.

(2) Water, dried yeast and the following vitamins: thiamin, riboflavin, pantothenic acid, niacin, pyrid-

oxin, folic acid (each 10 γ per ml.), biotin (0·14 γ per ml.). This was the optimum medium, and the development from egg to adult took 7·5 days. The mosquitoes were viable. Obviously 1·2 gm. of the best samples of yeast available did not contain sufficient of the above factors to produce viable adults.

(3) Liver extract and dried yeast (autoclaved) (Trager's medium for *A. ægypti*). Development from egg to adult took 14 days, and the adults were viable. Water extract of the same yeast and liver extract allowed development from egg to adult in 20 days; but the adults which emerged were not viable.

(4) Water, glucose (0·1 per cent), a mixture of salts (0·2 per cent), casein hydrolysate (2 per cent), the above-mentioned vitamin B complex (but with only 7·5 γ biotin per ml.) and ascorbic acid (150 γ per ml.). Although development on this medium was relatively slow (eggs to viable adults in 25 days) it proved to be the most suitable for studying the nutritional requirements of all stages of *Culex molestus*. Thus in the absence of pantothenic acid, all other factors being present, there was no development beyond the first instar; in the absence of thiamin, riboflavin or pyridoxin the larvæ die in the second instar; in the absence of folic acid, the larvæ reach the fourth instar but never pupate. In the absence of niacin, the whole developmental cycle lasts 42 days, and the adults are viable. In the absence of biotin the cycle lasts 36 days, but the adults are not viable. Ascorbic acid is not essential for complete development of viable mosquitoes, but in its absence the cycle is prolonged to 29 days.

It is interesting to note that the viable females raised on sterile media were autogenous and laid eggs in the absence of any kind of nutrition. Full details will be published elsewhere.

I wish to thank Prof. S. Adler for his advice and interest in this work.

Receptor Organs in Tunicata

NOTHING was known of tunicate receptors before 1899, when Herdman[1], in his description of *Ascidia*, mentioned a few structures that might act as receptors, but gave no proof or details. Lorleberg[2], on the other hand, stated in 1907 that in *Stylopsis* "there is complete lack of sense cells". Hecht[3] could not find any receptor organs besides the tentacles and margins of the siphons. Das[4] showed for the first time definite receptor cells in the test and mantle. He demonstrated red pigmented cells which act as photoreceptors. Besides these, the tentacles and dorsal tubercle have been mentioned by various workers as having definite receptor functions. I have found a new structure in *Ciona*, in the intersiphonal region, which appears like an eye-spot and is definitely a photoreceptor. No mention of this structure is found in the various accounts of *Ciona* given by different authors. This eye-spot can be easily seen when the atrial aperture is wide open. It lies on the wall of the mantle just behind the base of the atrial siphon on its dorsal aspect. It is specially conspicuous in dark-adapted animals.

I have made investigations on the receptor organs and the responses of the ascidians *Ciona, Ascidiella, Styelopsis* and *Herdmania*, to mechanical stimulation, gravity, light, temperature and osmotic pressure, a complete account of which is being published elsewhere. The main receptors in Tunicata are as follow:

1. *Tangoreceptors:* (*a*) cells scattered in the non-vascular areas of the test, especially the test of the siphons; (*b*) cells covering the ampullæ in the vascular areas of the test; (*c*) marginal cells, specially sensitive to vibrations of water or substratum, of the siphons; (*d*) tentacles. Stimulation of (*a*), (*b*) and (*c*) causes direct reflexes, while stimulation of (*d*) causes a crossed reflex.
2. *Photoreceptors:* (*a*) red pigmented squamous epithelium of the siphonal lining in all tunicates; (*b*) red-pigmented epithelium of the vascular ampullæ in Pyuridæ; (*c*) eye-spot in *Ciona*.
3. *Gusto- and olfacto-receptors:* (*a*) tentacles react to dilute acids, alkalis and different concentrations of sea-water; (*b*) dorsal tubercle—probably both for smell and taste (Metcalf and Hunter[5]).
4. *Rheoreceptors:* margins of the siphons—not only do the siphons bend to face a water-current, but they also bend upwards against gravity.
5. *Thermoreceptors:* the cells lining the siphons are very sensitive to changes in temperature, although the tentacles must also be an aid to the tunicate in registering temperature.

I have also demonstrated that, contrary to what was believed hitherto, Tunicata have positive as well as negative responses.

Site of Action of D.D.T. and Cause of Death after Acute D.D.T. Poisoning

EXPERIMENTS were carried out with *Periplaneta americana* and *Rana esculenta*, after injection with a D.D.T.-emulsion. Action-potentials from the n. cruralis (= 5th nerve, Pringle) of the second thoracic ganglion of *Periplaneta* were recorded with a special pre-amplifier and a cathode-ray oscillograph. No differences were found between normal and D.D.T.-treated animals in the following preparations: (1) crural nerve only connected with the second leg; (2) crural nerve only connected with the second thoracic ganglion, which was isolated from the other ganglia and from all peripheral nerves. Hence the D.D.T. causes no increase of spontaneous activity of the sense organs of the leg, nor of spontaneous motor-activity from the isolated ganglion. However, when the reflex path was intact (or partly intact—crural nerve connected with second leg and second thoracic ganglion), the action-potentials of D.D.T.-treated animals showed an abnormal increase in frequency.

These facts suggest that the specific action of D.D.T. is a facilitation of synaptic transmission. A direct proof of this assumption can be given with a 'spinal frog', where the homolateral contraction of the m. gastrocnemius was recorded after stimulation of the peripheral stump of the n. ischiadicus, and the contralateral reaction (through the spinal cord) after stimulation of the central stump of the same nerve. It is well known that a contralateral response does not follow one single induction shock; two or even more shocks being necessary to activate the motoneurones. After D.D.T. treatment, however, one single stimulus, even a weak one, induces a high contralateral contraction. This phenomenon was studied in a wide variety of experiments, with different kinds of stimulation. These experiments show that the specific cause of D.D.T. symptoms is a facilitation of synaptic transmission. The question arises whether this fact can explain the cause of death after D.D.T. poisoning.

The answer is given by the same kind of experiments, carried out at a later stage of poisoning. The preparations then fail to give any contralateral response, even after faradic stimulation, while stimulation of the peripheral stump of the sciatic nerve (of the same animal) causes a normal reaction. Thus, a period of synaptic facilitation is followed by a synaptic block. This synaptic inhibition is, of course, not restricted to the sciatic region of the spinal cord, but represents a general blocking action of D.D.T., which causes the death of the animal.

The production of central inhibition could also be recorded with *Periplaneta*, although it takes a longer time to become perceptible. Besides the action of D.D.T. on the central nervous system, there is evidence of a specific action on the myoneural junctions or on the muscles of the leg of the cockroach. This will be discussed elsewhere.

On the other hand, D.D.T. had no specific action on the sense organs of the leg of *Periplaneta* or *Rana* (either skin-receptors and proprio-receptors), or on the peripheral nerves, or on the electro-encephalogram of *Rana*.

Experiments to detect any action of D.D.T. on the spontaneous activity of the nerve cord of *Periplaneta* are in progress, although the facts mentioned above make the existence of such an action improbable.

These investigations were carried out under the auspices of the National Council for Agricultural Research (Toegepast Natuurwetenschappelijk Onderzoek). Details of the work will be published elsewhere.

Occurrence of *Acanthocephalus ranæ* Schrank. in Great Britain

Acanthocephalus ranæ Schrank. (= *Echinorhynchus ranæ* Schrank. = *Echinorhynchus hæruca* Rudolphi.), the only known Acanthocephalan parasite of the frog, has rarely been found in Great Britain. The only known recorded occurrences are by Elmhirst[1], who found it in the common frog *Rana t. temporaria*, and Baylis[2], who records its occurrence from Westmorland in a 'newt' and in the common toad.

Twenty-seven specimens were discovered in the duodenum of a single frog (*Rana t. temporaria*) during a routine dissection in November 1947. Unfortunately, frogs from two localities were mixed before examination, and the infected frog may have come from either Carnki (Cornwall) or from Newdigate (Surrey). Nineteen of the individuals were measured while still alive, and were found to consist of both males and females; males 7·0–10·0 mm., females 17·0–35·0 mm. Of the nineteen individuals determined, seven were males and twelve females. Mature eggs were present in all the females examined, and were extruded from one specimen on removal to saline. None of the males had the bursa copulatrix extruded, and all were hanging free in the lumen of the duodenum when discovered.

In the few individuals examined, the number of proboscis hooks and longitudinal hook-rows corresponded with the results of Lühe (*vide* Meyer[3]) for German specimens—females having 18 longitudinal rows and the males 13 longitudinal rows, with four to six hooks in each row—rather than with the figures given by Van Cleave and Porta (*vide* Meyer[3]). Van Cleave found in four individuals examined 12 longitudinal rows with six to seven hooks in each row, and this appears to agree with Porta's figures[4].

Although the recorded instances of the occurrence of this parasite seem to be rare, this may be due to lack of observation. In Germany and Austria the parasite is common in newts, toads and salamanders, as well as in the common frog. Heavy infections in *Rana t. temporaria* L. (as much as 50 per cent) occur in Germany[3]; but it appears to be much less common in France and Italy. It has been recorded only once in North America (Van Cleave[4]) from *Diemyctylus viridescens* at Baltimore, Maryland. Van Cleave considered the parasite to be rare in North America, as subsequent examination of Amphibia failed to reveal further specimens. This rarity is possibly correlated with the absence of the secondary host *Asellus aquaticus* L., which though common throughout Europe has been recorded in America only in Labrador and at Hopedale[5]. *A. ranæ* was recorded from the Dnjepr by Kostylew (*vide* Meyer[3]), in 1926.

It is hoped that further research and more careful observation of British Amphibia will throw more light on the distribution of this interesting species.

Colpomenia sinuosa (Mert.) Derb. et Sol. in Scotland

I wish to record the finding of *Colpomenia sinuosa* (Mert.) Derb. et Sol., near Stornoway in the Isle of Lewis. The plants were found growing in shallow pools on *Corallina officinalis* L. at Aignish, on the Broad Bay side of the Eye Peninsula in July 1947.

The first record of this alga in Scottish waters was made by Dr. M. D. Dunn[1], who found it at St. Andrews in the summer of 1938. As it is now known to occur all round the Irish coast[2], these two Scottish records show that it may also be found elsewhere on the coast of Scotland.

I would be pleased to hear of any other Scottish stations for this alga, so that its distribution in Scotland may be known.

Abnormal Serum Protein in Parenchymatous Liver Diseases

Several colloidal serum reactions have been proposed during recent years for revealing damage of the liver parenchyme: the cephalin-test (Hanger), the colloidal gold and thymol tests (Maclagan) and the colloidal benzoin and shellac tests[1]. Most authors suppose that increased gamma-globulin forms the basis of these tests, but it has been suggested that beta-globulin may be responsible, too.

In fractionation experiments with variable concentrations of alcohol at low temperature (5–10° C.), we found that normal sera caused precipitation only in alcohol concentrations higher than 20 per cent; sera of hepatic cases, on the other hand, gave precipitations in 5–10 per cent alcohol. No precipitation occurs when alcohol is diluted with 0·9–10 per cent sodium chloride or when twice-distilled water is added without alcohol, or when the *p*H of the diluted alcohol is less than 5·5.

The protein fraction precipitated with 10 per cent alcohol is insoluble in water, but is readily soluble in 0·9 per cent sodium chloride; it is partly precipitated with 30 per cent saturated, and completely precipitated with 50 per cent saturated, ammonium sulphate. Saturated sodium chloride solution precipitates the greater part of it. The iso-electric point is about *p*H 5·5. The tryptophane content varies between 3·0 and 3·8 per cent. The serum concentration of this fraction, present in all cases of parenchymatous hepatic damage, amounts to 1–3 per cent, forming a considerable part (30–50 per cent) of the total globulin.

The purified fraction gives positive colloidal gold, benzoin and Takata tests of the same intensity as does the corresponding quantity of serum; with the remaining, non-precipitable protein, colloidal tests give negative results. The effect of the isolated fraction on thymol turbidity is somewhat less than that caused by the corresponding quantity of serum. In Weltmann's coagulation test, on the other hand, the isolated fraction is coagulated in presence of 0·1 per mille calcium chloride; the higher values (0·2–0·4 per mille calcium chloride) obtained with total serum are the consequence of some unknown factor hindering coagulation.

Increased Muscle Phosphorylase Activity in the Starved Rat

It was shown earlier that glucose uptake in the isolated rat diaphragm was reduced after a period of non-carbohydrate, high-fat diet[1], and that a spontaneous regulation of food intake took place in animals shifted from such a diet to a high-carbohydrate diet[2]. These physiological changes occurring after a period of carbohydrate deprivation, together with many other observations after starvation or fat-feeding by other investigators, suggest that the kind of foodstuff taken by the animal (or human subject) determines in some way the metabolic pattern.

It is known that a decrease in insulin content of the pancreas is found after starvation or following a fat diet[3]. Many observations seem, however, to point to the fact that the change in the metabolic pattern can take place independently of the hormonal status, for example, the dependence of the glucose-tolerance curve[4,5] and the rate of depletion of glycogen stores[6] on the previous carbohydrate intake in the hypophysectomized animal. It is conceivable that a difference in cellular enzymatic activity is found in different metabolic conditions.

To investigate this problem we have undertaken a study of muscle phosphorylase activity in fed animals, in starved animals, and in animals on diets containing different amounts of carbohydrate. The results obtained in fasting animals will be given briefly here.

Phosphorylase activity was studied by the method of Cori, Cori and Green[7], determining the liberation of phosphate during the process

glucose-1-phosphate → glycogen + phosphate.

A crude extract of rat muscle was made after freezing with liquid air. The extract was filtered, adjusted to *p*H 6·1, and dialysed against running tap water. The dialysed extract was diluted with a weak solution of cysteine and added to tubes containing glucose-1-phosphate, glycogen and cysteine-glycerophosphate buffer. To some tubes adenylic acid was added. The tubes were agitated for one hour at 31° C. in a Warburg bath. After treatment with trichloracetic acid and filtering, the phosphate formed during the incubation period was determined as the difference between a zero value and a 60-min. value. The protein content of the enzyme extract was estimated by the biuret method, standardized against human serum. In each experiment the muscle phosphorylase activity was observed in one fed and one fasted animal.

The effect of fasting is shown in the accompanying table. The activity, both with and without adenylic acid, is consistently higher in the fasted animals.

Muscle phosphorylase activity in fed and fasted rats

	Fed			Fasted			
Number of experiment	Phosphorus liberated (γ) 1*	Phosphorus liberated (γ) 2†	Protein in reaction mixture (mgm.)	Phosphorus liberated (γ) 1*	Phosphorus liberated (γ) 2†	Protein in reaction mixture (mgm.)	Duration of fast (days)
1	132	256	—	708	862	—	2
2	80	304	5·8	304	278	6·2	3
3	34	56	5·6	174	214	5·4	2
4	170	540	5·2	618	632	5·2	3
5	33	75	5·8	284	412	5·4	1
6	12	170	6·4	198	282	5·8	5
7	54	246	6·6	374	744	6·6	2
8	44	146	5·6	164	298	6·0	2

*Without added adenylic acid. †Adenylic acid added.

We are not suggesting, at present, any definite explanation for the higher phosphorylase activity in the starved animals. Studies are now being conducted on the phosphorylase activity during refeeding after fasting, in animals on diets containing different amounts of carbohydrate, and in animals shifted over from a low- or non-carbohydrate diet to a diet containing large amounts of carbohydrate (starvation diabetes). It is proposed to investigate other enzyme systems in intermediary carbohydrate metabolism, for example, the hexokinase system and the system of oxidative phosphorylation in animals on different dietary regimes.

The results obtained appear to indicate profound changes in the pattern of intermediary carbohydrate lism depending upon the previous food intake animal. They may help towards a better tanding of the factors governing the metabolic ys on different diets, and especially the many ccumulated on the effect of fasting or fat- on carbohydrate metabolism. In general, stress the importance of ascertaining the onal status of the animal in carrying out tic studies.

tailed report will appear elsewhere. We wish ess our appreciation to Prof. E. Lundsgaard s interest and helpful counsel in conducting experiments.

ple Method for Direct Comparison of the ssant Effect of the Barbiturates on the Respiration and Circulation

26, Knaffl-Lenz[1] introduced a method for the of digitalis preparations by determining the lethal dose on intravenous injection in tized guinea pigs. The method, which may for all kinds of cardiac glucosides, has since official in, for example, Britain[2] and Sweden[3]. g to this procedure, the solution to be tested uced into the vena jugularis under constant and at constant speed (either from a burette Aariotte stopper or with a motor-driven apparatus). The lethal dose is determined observation of the cardiac standstill (con- e details of the procedure, see, for example, nss Bech[5] and Goldberg[6]). The number of equired is determined by the degree of one wishes to give the results; this may ted with the help of the usual statistical

r method can also be used for comparison ressant effect of the barbiturates on the and circulation. The guinea pigs in this næsthetized with urethane. The dose re- roduce cessation of the respiration may be by direct observation, although a self- device is, of course, also possible. When ceases, the dose and time are noted, the opened and artificial respiration by a prepared connexion between the trachea ing pump is started. The cessation of ivity is observed as in the Knaffl-Lenz the dose and time required are noted. quired for the cessation of respiration tivity are thus determined on one and l. The concentration of barbiturate, in solution in the form of an alkali t the dose required for the cessation vity will be about 1 ml. per 100 gm. body-weight. The suitable rate of injection will then be approximately 0·5 ml. per min.

Doses required to produce cessation of respiration and circulation in guinea pigs after intravenous injection of some common barbiturates

Barbiturate	Concentration (per cent)	No. of animals	Dose for respiratory standstill (R) (ml./100 gm. body-weight)	Dose for cardiac standstill (C) (ml./100 gm. body-wt.)	R/C (as percentage)
Sodium 5-*iso*-amyl-5-ethyl-barbiturate ('Amytal sodium')	2·75	17	0·18±0·019	0·75±0·019	24
Sodium *N*-methyl-cyclo-hexenylmethyl barbiturate ('Evipal sodium')	2·2	7	0·055±0·015	0·98±0·039	6
Sodium *iso*propyl-β-brom-allyl-N-methyl-barbiturate ('Narkotal')	2·2	14	0·055±0·0042	0·72±0·030	8
Sodium 5-ethyl-5-(1-methyl-butyl)-thio-barbiturate ('Pentothal sodium')	1·2	9	0·058±0·0057	1·02±0·048	6

A simple method for such comparisons is of great practical value, since it has proved that the depressant effect of the barbiturates on the respiration has shown a tendency to increase if their duration of action is diminished.

In the accompanying table are given the results of a number of experiments using the method described. 'Amytal', with its moderate duration, has been compared with intravenous anæsthetics of ultra-short duration, such as 'Evipal', 'Narkotal' and 'Pentothal'. The depressant effect on the respiration of the last three preparations when injected intravenously is, as seen from the table, both absolutely and relatively in a totally different class from that of 'Amytal'. The dose required for cessation of circulation is in the case of 'Amytal' about four times as great as the dose inhibiting the respiration, while the corresponding value for the three other compounds is about fifteen times.

The importance of artificial respiration after cessation of spontaneous respiration under intravenous barbiturate anæsthesia is demonstrated, in short, in an extremely striking way. The margin between cessation of respiration and cardiac activity respectively brought about by compounds of the 'Amytal'-type is not as favourable for a successful treatment with artificial respiration, although this is far from insignificant. For these preparations, which are chiefly used in ambulant practice and are administered by mouth, the considerably smaller absolute toxicity on the respiratory centre is of all the greater importance. It is, of course, as a matter of fact, this form of toxic effect which determines the practical usability of the ordinary hypnotics.

Esterification of Phthalic Anhydride with Primary Alcohols at Room Temperature

In a recent publication[1], some investigations on the esterification-rate of dibasic acid anhydrides with primary alcohols at room temperature were recorded. From the results of titration of acid anhydrides dissolved in the cold in primary alcohols, using a solution of potassium hydroxide in the alcohol as titrating agent, it was concluded that mono-ester formation was instantaneous and quantitative, being so rapid that comparison of rates of reaction was impossible.

We have attempted to utilize this apparently instantaneous reaction in the preparation of certain half-esters of phthalic acid, but soon discovered that the expected product was only obtained in very small yields, if at all. Even after prolonged periods, substantial amounts of unchanged phthalic anhydride were recovered from the mixture. Titration of the mixture by the method of Siegel and Moran did, however, give results in agreement with the formation of a half-ester.

We consider that these apparently contradictory findings become reconciled if the esterification reaction is catalysed by the addition of the titrating agent. It is therefore incorrect to conclude that mono-esterification of a dibasic acid anhydride with a primary alcohol proceeds instantaneously and quantitatively at room temperature, as it only does so after the addition of potassium hydroxide, that is, in the presence of a catalyst.

Photolysis of Organic Disulphides

The reactions following light absorption by pure organic disulphides in solution have not been studied, although the reactions are of great importance in the chemistry of wool, affecting both felting and shrinkage of the wool[1,2]. Similar reactions occur in irradiated milk[3] and in petrol[4].

The absorption spectra of diphenyl-, di-*o*-tolyl-, and di-*p*-tolyl- disulphides were found to be similar. Absorption occurred below *c.* 3,000 A., with $\lambda_{\max.} =$ 2,450 A.

Solutions of all three in organic solvents, as well as cystine in 3 per cent hydrochloric acid, were exposed to filtered light from a 125-W. mercury vapour street lamp from which the glass envelope had been removed. Measurements of the light flux by uranyl oxalate actinometry gave results in good agreement with those obtained using a thermopile–galvanometer combination. It was found that the disulphides were converted into the corresponding thiols, identified by the melting points of their metallic derivatives and estimated by amperometric titration with silver nitrate. The solvent was variously alcohol, *n*-hexane and ether.

In view of the theory[1,2] which accounts for the acidity developed in irradiated wool by the presence of sulphuric acid produced from hydrogen sulphide, which in turn came from a disulphide by chemical reaction, tests were made repeat determine whether hydrogen sulphide was in these reactions also; but no trace of any w Nor was sulphur a product, air having been from the reaction vessel.

The quantum yield of thiol formation was 0·003 for diphenyl-, di-*o*-tolyl- and disulphides respectively, and 0·020 for c hydrochloric acid. It was independent perimental error (*a*) of the nature of the a (*b*) of the concentration of the disulphide, the nature of the solvent used. The lo for the cystine is explained by the simu liberation of ammonia in this case[5].

The following mechanism is adequate if a radical *R*—S— be assumed formed, as has been in another case[6]. Free-radical formation is ene ally possible with light of wave-length less 4470 A., taking the energy of the SS bond 63·8 k.cal./mole.

$$\begin{array}{lcl} R\text{—S—S—}R & \xrightarrow{h\nu} & R\text{—S—S—}R^{*} \\ R\text{—S—S—}R^{*} & \rightarrow & 2\,R\text{—S—} \\ R\text{—S—} + M & \rightarrow & R\text{—SH} \\ R\text{—S—S—}R^{*} + M & \rightarrow & R\text{—S—S—}R, \end{array}$$

where *M* is a solvent molecule. Reaction *D* the fact that the quantum yield of thiol fo is less than 1. Its value indicates that an a molecule has one chance in 44 of decomposin it is deactivated by collision.

I am indebted to the Commonwealth Committee for a grant which made possible chase of equipment used.

ATOMIC ENERGY AND SOCIETY

conference of the Atomic Scientists' Asso- on on "Atomic Energy and Society" and Energy and the Scientist" was held in the Hall, London, on October 30. A number of shed men of science addressed the con- and their speeches were followed by a general While there was general agreement ons of scientific fact, the different speakers idely different interpretations upon the ational and international difficulties with control, secrecy and individual freedom, reflected to a large extent their different cal outlooks. Prof. R. E. Peierls in his open- emarks emphasized that the Association as does not adhere to any particular political sophy; its primary function is to spread a ledge of the facts and to provide a platform discussion.

spects for the use of atomic energy in peace eviewed by Prof. M. H. L. Pryce. Radioactive s, manufactured in atomic piles, have already of great value, particularly in medicine and gical and chemical research, for tracing the of reactions by the principle of marked atoms. pplications require relatively small quantities pactive materials; the present Harwell pile be able to satisfy all European needs. On the and, for the generation of electric power in es sufficient for industrial purposes, much quantities of fissile material would be needed ities that could readily be used for the tion of bombs if required. Many technical s remain to be solved before atomic power an be put into operation, and it is not yet that adequate supplies of the nuclear fuel obtained, either by separation of uranium- natural uranium or by the process of ' from uranium-238, or from thorium. ic age may still be half a century away.

M. S. Blackett gave what he described as itten' analysis of the probable effects of ombs in future warfare. For some time to mbs would be delivered to their targets by onal aircraft, which would presumably have e hundreds of miles over enemy territory, o attack by much faster jet fighters. With ament of at least ten planes for each target mutual protection, the number of aircraft to launch a surprise 'annihilation' raid a country's industrial centres would be thousand; preparations for an attack on scale could be detected and would lead to The effect of a single atomic bomb was nt to about 2,000 lb. of ordinary bombs; e than 1,000,000 lb. of bombs were dropped pe in the Second World War without es causing Germany to surrender. Russia far more severely than that from the German on, yet was able to fight on to victory. Thus, Blackett's opinion, it cannot be assumed bombs would bring rapid or even eventual war', and to embark on a conduct diplomacy by using it be very dangerous and could only despair.

aker was Sir George Thomson, who of the prolonged negotiations for atomic energy which had taken place in the United Nations Atomic Energy Commission and in its technical committee, on which he was the British representative. Only once was this committee able to sign a unanimous report; but this report did contain the vital statement that control is technically feasible. For the rest there had been interminable wrangling. The Russians would begin with obviously impossible demands, such as the one that the United States should destroy its stock-pile before control was established, and then make grudging concessions so late that the other Powers had some cause for doubting their sincerity. Nevertheless, Sir George thinks it is essential to continue the attempt to establish control, so that a country might have at least the security of a few months warning if an attack with atomic bombs was being prepared against it.

Prof. N. F. Mott referred to the need for maintaining contact so far as possible with scientific workers in the U.S.S.R. and other countries. He agreed with Prof. Blackett that the use of atomic bombs would not bring speedy victory in another war, and pleaded for moderation and a spirit of compromise in the negotiations. The extremists were beyond the reach of argument; but ordinary people could be made to understand that there are common needs transcending all our differences.

In the discussion that concluded the first session, Dr. E. U. Condon, a welcome visitor from the United States, commented on the widespread belief that military strength is our only defence against Communism. He believed it is equally important to have a positive social policy, to show in practice that Western democracy provides a better and happier way of living. Other speakers asked Prof. Blackett to elaborate some of his points, and there was both criticism and defence of his allegedly 'pro-Soviet' outlook. The question of the control of bacteriological weapons was also raised: Sir George Thomson replied that he believed control would be far more difficult in that case, and that it would probably be best to make a beginning with atomic energy by itself.

The second session of the conference was concerned with the effect which the development of atomic energy has had upon the individual scientific worker. Prof. Peierls described the difficult position which many men of science now occupy. On one hand, they are entrusted with secret information that affects national security; on the other hand, they belong to the international community of science, which is pledged to the free exchange of ideas. It has been possible to maintain this dual role only because at present the information which has to be kept secret does not have any particular bearing on the fundamental problems which interest the pure scientist. Information must be either secret or wholly international; it cannot be restricted, for example, to the west of the Iron Curtain. The participation of Eastern scientific workers in helping to solve our fundamental problems would always be welcome, even though they, like ourselves, might not be permitted to discuss certain things. We must accept the professional work even of individual scientific men whose personal political integrity may be in doubt; and in Britain, while the military authorities must decide whom they can trust with military secrets, scientific workers doing ordinary academic work should have the same freedom as other citizens, if individual liberty is to be preserved.

Sir Henry Dale described the progressive restrictions which have been imposed on the freedom of science in the last fifty years, in consequence of its increasing military importance. He said that the ideal of complete freedom should be strenuously maintained, and that in the present difficult circumstances the boundary between the free and the secret knowledge should be kept as sharp as possible. One of the most distressing features of the present time, he said, is that scientific men in some countries are required not merely to conform to a political orthodoxy but also to uphold specific scientific doctrines for political rather than scientific reasons. A notorious instance is the genetics controversy in the U.S.S.R., in which the opponents of Lysenko, in particular Vavilov, have been dismissed from their posts or disappeared. Where scientific men are bound in their professional views by political considerations, scientific co-operation is obviously impossible.

Dr. E. H. Burhop considered that the type of interference with individual freedom represented by the Thomas Committee on Un-American Activities is a serious danger in the Western world. The conference ended with a lengthy discussion, devoted largely to the points raised by Sir Henry Dale on scientific freedom in the U.S.S.R. and on the merits of Soviet genetics.

H. R. ALLAN

THE PLACE OF BIOLOGY IN A CURRICULUM*

By PROF. H. GRAHAM CANNON, F.R.S.

IN the teaching of biology there are two sharply defined aspects: there is the study of the structure of organisms correlated with their functioning, leading to knowledge of human physiology and the relation of man to the animal and plant kingdom. This may be looked on as a factual aspect while, on the other hand, there is the study of evolution and all that it implies and involves. This may be regarded as a cultural aspect.

To take the factual aspect first. If there is one thing more than any other with which a child is intimately associated it is with its own body. Its body should become its immediate concern, and all school children, whatever other subjects they may study, should be taught to understand in a simple manner its mechanism and structure. But this is far from being the case, for we still live in an age of extraordinary prudery in which it is improper to discuss anatomical and functional details. This is brought out only too clearly when it is realized that there are no words in ordinary use to describe such natural processes as defæcation or micturition, and as regards the parts of the body, there are no names in ordinary use for the external genital organs. Any words there may be are considered completely vulgar. Now a general elementary study of the human body taken as an ordinary subject for study, quite apart from the educative value that the child derives from knowing what happens inside its own body when, say, a meal is taken, or when a schoolboy collapses exhausted after a hundred yards sprint—quite apart from this, the mere fact of taking this sort of study along with his history or his language or his science would make him feel that here is something quite ordinary and not in any way exceptional. He will then feel free to discuss biological things, things about himself, in an open manner, just as he would without hesitation discuss a problem of mechanics or history. In many schools it is the custom to have a visiting teacher, often a doctor, who appears spasmodically to give short courses of lectures to the older students on what is sometimes called 'personal hygiene'; but this is all wrong. He comes to talk to the students about sex, and that is where the harm is done. Why should sex be singled out like this? Why separate the gut from the genital system? We professional biologists do not, and neither do university biological students. It is this separation of the problem of the human body from the other subjects of study that tends to reinforce the Victorian prudery that we have inherited and to retain those awkward complexes resulting from suppressions which are the curse of adolescent education.

Now as regards biology as a cultural subject, this is the aspect that I consider of such value to the student who is to specialize on the Arts side. All syllabuses, whether good or bad, start from the 'lower' or structurally simple and lead up to the 'higher' or complex advanced types. If this evolutionary story is properly dealt with, not as a series of separate steps but rather as a gradual unfolding from simple beginnings of the complex organisations that we see at the top of the tree, then a student derives a new conception of life as a whole. He realizes that it is not only animals and plants that have evolved, but also all other things such as food and clothes, houses and motor-cars and, more important still, mental and social activities. Civilization, in fact, that he sees around him, he realizes is something that has gradually evolved and which he has inherited. The effect of this broad outlook on his other subjects cannot be over-estimated. How often is a student at school learning a language made to understand that that language has evolved? Or, worse still, how often is the school-child, working at some narrowly circumscribed period of history for the School Certificate examination, impressed with the fact that history *is* the evolution of mankind?

These, then, are the two main reasons why I consider biology should be a subject taught throughout the school and to all types of children. It is considered proper by all educationists that certain fundamental subjects such as arithmetic and English form an absolutely necessary part of any school curriculum. Has not the time arrived when it is just as important that the school-child, or the adult, for that matter, should know how his own body and his own society work as that he should know how to calculate compound interest or speak the king's English?

The views I have put forward are nothing more than ideal views. So long as schools are tied down and cramped in their style by having to conform to syllabuses of matriculation boards or standards of university scholarships, it is clear that it is not possible to devote the necessary time and teaching man-power to deal with biology as I have indicated. In 'modern' schools, however, where public examinations are not the determining factor in the teaching curriculum, there is some hope that a broad treatment of biology may be possible.

There is another and most important direction in which valuable biological teaching can be carried out, and that is in adult education. What I have said of the value of a biological outlook to the school-child applies *a fortiori* to the adult. But here again, extramural university teaching is largely bound up with the Workers' Educational Association. This excellent educational organisation, however, is hampered by the constitutional custom that the adult students *ask* for whatever classes they feel they want. As a result, adult education has come to be looked on as largely a development of the Faculty of Arts. The grown-ups ask for subjects such as psychology and economics, that naturally appear to them to bear directly upon their own lives. They do not realize that the subjects they choose are, as often as not, far beyond their mental capacity; in fact, as some of us think, they are beyond the capacity of the ordinary undergraduate. If they could be encouraged to study in a simple and broad manner the elements of biology, then a great step forward could be made in education generally.

* Part of an address at a joint session of Sections D and L of the British Association meeting at Brighton on September 14.

CHROMATOGRAPHY FOR GENERAL CHEMICAL ANALYSIS

ORIGINALLY used for coloured substances, chromatography has been extended to deal with a wide range of colourless materials, by the use of suitable coloured derivatives or of indicators. Sugars and related substances form an important class of this kind, for which chromatography has proved to be a powerful analytical tool, particularly within the last ten years.

Messrs. Binkley and Wolfram* have themselves made important contributions to the subject, and their pamphlet appears at an appropriate time, when work in this field is expanding so rapidly; it provides carbohydrate investigators with an up-to-date historical review and practical details of the techniques involved. The first section of this pamphlet gives a simple general description of the adsorption chromatogram, with various details, such as selection of adsorbents, construction and operation of the chromatogram and location of zones after development. The second section provides a comprehensive review of the literature up to the end of 1947. Most of this section deals, of course, with adsorption chromatography, since it is only very recently that partition chromatography, particularly on paper, has been applied to the sugars. The third section describes with experimental details some of the applications of chromatography to sugars; for example, resolution and quantitative estimation of mixtures, purification, control in the production of technical sugar products and end-group assay.

Similar in size and presentation, "Introductory Notes on Chromatography"† covers a much wider field, including vitamins, alkaloids, chlorophylls, carotenoids, vegetable and mineral oils, amino-acids, inorganic ions and many other substances. Some of the applications are given detailed treatment in order to illustrate methods suitable for use in analogous cases. A useful list of references is given, most of which occur within the last ten years, and, as in the case of the first pamphlet, most of the chromatography described is of the adsorption type. This pamphlet succeeds in condensing a great deal of information into its forty pages and will be found useful as an introduction to the well-known textbooks on chromatography.

Workers in both academic and industrial fields will find information of value in these two pamphlets, which are clearly written and attractively produced. Those who have not already adopted chromatographic techniques will be encouraged to do so after reading them. Chromatography may well prove to be indispensable in many investigations.

During the past year, the range of separations has been greatly widened by the partition chromatogram and by chromatograms which are neither clearly adsorption nor partition. Among recent advances in chromatography may be mentioned the use of dinitrophenyl derivatives of amino-acids and peptides, the use of radioactive isotopes, and the employment of new kinds of supporting media or modifications of existing media in partition chromatograms for the purpose of dealing with non-aqueous solvent systems. The present period is thus one of rapid development, and it is therefore desirable that information on the most recent advances in chromatography should be made available from time to time and with little delay. Perhaps this information might be issued in the form of pamphlets similar to those reviewed here.

R. CONSDEN

NEW CHEMICAL LABORATORIES AT UNIVERSITY COLLEGE, DUBLIN

By PROF. T. S. WHEELER

THE honours degree courses in science in University College, Dublin, have recently been extended by one year so as to require four years of post-matriculation work. After three years, the student sits for a general degree examination in three subjects, and if he passes and attains an honours level in a subject is admitted to the honours school in that subject. A number of students, however, who wish to become chemists pass the general degree examination at a level in chemistry insufficient to qualify for admission to the honours school. For those and for other students, who though qualified for honours study feel attracted towards industrial chemistry, there has been instituted a course which extends over one year and leads to a diploma in chemical technology. To provide accommodation for the two types of fourth-year students two new chemical laboratories have been opened (see *Nature*, November 13, p. 768), the Ryan Laboratory for honours degree students and the Nolan Laboratory for those taking chemical technology.

The Ryan Laboratory commemorates the late Prof. Hugh Ryan, who was professor of chemistry in the College during 1899–1931 and who initiated honours degree teaching there. The laboratory has a floor area of 460 sq. ft. and will accommodate up to ten students; as formal lectures to honours candidates are limited to five per week, a large proportion of the students' time is spent in the laboratory. There is no specialization between the three main branches of chemistry in the fourth year, and in the Ryan Laboratory normal advanced work in inorganic and organic chemistry is carried out; practical physical chemistry is done in a special laboratory. Emphasis is laid on quantitative inorganic analysis and on organic preparations involving modern methods of reduction, oxidation, condensation and so on. Short courses are also given on the application of semi-micro methods in both branches of chemistry. A reasonable variety of modern physico-chemical apparatus is available, the equipment including an absorptiometer (Spekker), a spectrophotometer (Coleman), microphotometer and spectroscope (Hilger), a chromatographic apparatus, an ultra-violet lamp and electrometric titration apparatus. A special feature is made of vacuum distillation; there are in the department molecular stills and various pumps, including a mercury pump combination (Towers) giving pressure of the order of 1 millibar. A laboratory fractionation column (Todd) has an efficiency of fifty theoretical plates. Each student gets an opportunity of making himself acquainted with the manipulation of the various pieces of apparatus.

The lecture courses and associated reading for the honours degree follow normal lines; electronic theory may perhaps be regarded as a special feature. The students attend a series of lectures extending throughout the year in which the quantum mechanics of the hydrogen atom, bond formation, the periodic table and atomic structure, and applications of electron theory in organic chemistry are discussed in some detail. It has been found that the three-year general course, which includes physics and mathematics to a good pass-degree standard, is useful to the student in reading modern theoretical chemistry.

Students who obtain an honours degree may enter the research laboratories to work for the M.Sc. degree; the work normally occupies one year. Various themes are studied; but at present the main work involves a study of the mechanism of base-catalysed reactions of the Claisen type with special reference to transformation reactions (see, for example, *Proc. Roy. Dublin Soc.*, 24, 291; 1948).

The Nolan Laboratory (floor area 1,000 sq. ft.) is called after the late Prof. T. J. Nolan, who was professor of chemistry in the College during 1932–45. Prior to his comparatively early death, he had in conjunction with Prof. M. A. Hogan, professor of mechanical engineering, worked out the details of the course in chemical technology, but owing to the War was unable to make arrangements for the institution of the course. The laboratory contains apparatus to illustrate various unit chemical processes; this includes a centrifuge, a high-pressure (350 atmos. at 350°) autoclave of 5 litres capacity equipped with a stirring device and gas inlet (Cook), a 'Pyrex' glass fractionating column 3 ft. high, a steam-heated pan, a filter press, grinding equipment, high-temperature and vacuum ovens, and metering apparatus. Low-pressure steam and the other usual services are provided. The students receive lectures on the unit chemical operations which they study in the laboratory. At least half their time is spent in the Engineering Department of the College, where they have lecture courses on thermodynamics, materials of construction, workshop practice, fuel technology and electrotechnology. They also have practical instruction in the foundry, workshop, drawing office, and fuel and electrical laboratories.

In connexion with the planning of both the academic and industrial courses, it is desired to acknowledge valuable advice received from the heads of departments of a number of universities and colleges in Great Britain and from the Institution of Chemical Engineers.

PREHISTORIC FLOODING IN THE SOMERSET LEVELS

THE post-glacial history of the Somerset Levels has been the subject of considerable published work by Prof. H. Godwin and his collaborators in the pollen-analysis of peat; but a new series of "Studies of the Post-Glacial History of British Vegetation" reveals such a dramatic story as to appeal to more than specialists alone, although pollen-analysis and the study of macroscopical remains provide the scientific background of dating.

The unearthing and investigation of four distinct trackways through the raised bogs which lie between the Polden Hills and Wedmore Ridge are described in the first paper by Prof. A. R. Clapham and Prof. Godwin (*Phil. Trans. Roy. Soc. London*, B, 233, 233–273; 1948). Each is of particular interest, for, although appearing to be roughly contemporaneous, all represent different types of construction. The Meare Heath trackway is composed of transverse baulks of timber (mostly oak), many of which are perforated by mortise holes holding sharpened vertical piles. Long squared wooden stringers formed the margins of the track and indicate the use of wheeled traffic. The Shapwick Heath trackway, on the other hand, is of brushwood kept in place by stakes of various origins but including beech. Another trackway at Westhay is constructed from birch stems, the majority of which are laid longitudinally together with shaped, vertical stakes driven in to pin loose brushwood which prevented lateral displacement of the timbers. The shape of the axe-cuts on these timbers indicates a Late Bronze Age dating which is confirmed by other archæological remains. The Blakeway Farm trackway consists of overlapping faggots of very straight hazel poles which there is every reason to believe were derived from trees grown in a woodland system similar in its effects to present-day coppicing.

Each trackway was built upon the surface of a dry *Sphagnum-Calluna* bog; but in every case this appears to have been overwhelmed by flooding with the eventual formation of eutrophic *Cladium* fen. It is especially significant that they appear to have been submerged before suffering much hard wear, and a dramatic picture is drawn of the calamitous flooding of river- and lake-side colonies which caused a mass-evacuation over the improvised tracks.

The complementary paper by Prof. Godwin (*Phil. Trans. Roy. Soc. London*, B, 233, 275–286; 1948) concerns the correlation between climate, forest-composition and prehistoric agriculture in the Somerset Levels. The most intense phases of agricultural activity appear to have occurred in the Middle and Late Bronze Ages and between Middle Iron Age and Middle Romano-British times, each being terminated by flooding of the raised bogs. Climatic change and not agricultural clearance is held to be the cause of changes in forest composition at the first flooding. The general nature of 'recurrence surfaces' is discussed, and it is pointed out that active bog-growth ceased in Romano-British times; but again this appears to have been the result of flooding by base-rich or brackish water and not an effect of Roman drainage schemes. The striking abundance of the remains of *Scheuzeria palustris* at the flooding surfaces contrasts strongly with its great scarcity at the present day (which is greater even than Prof. Godwin mentions, the species being extinct in

England according to a forthcoming paper by Dr. W. A. Sledge in *Watsonia*).

Finally, a probable Early Iron Age dating for the monoxylous 'Shapwick Boat' is based upon the pollen-analysis of a sample of peat taken from the boat, and rounds off very neatly these outstanding contributions to the history of primitive man and his environment in Somerset. H. G. BAKER

PLASTICS INDUSTRY IN SCOTLAND*

THE reconstituted Committee on Plastics appointed by the Scottish Council (Development and Industry) was appointed to inquire further into the extent to which the industry is being developed in Scotland to meet requirements, to suggest what further action is required to meet the situation, and to consider in particular the possibilities of meeting the basic requirements of the industry from raw materials in Scotland. In its final report, the Committee states that while more firms are now manufacturing finished materials from moulding powders obtained from elsewhere, and the engineering industry is in a position to tackle the highly specialized side of mould fabrication without difficulty, no developments of any kind have occurred in the manufacture of the ingredients of the moulding powders. No plastics industry can be firmly established in Scotland while these raw materials have to be imported, and the supply of coal-tar phenol and cresols is quite inadequate to meet the needs of the plastics and other industries of the United Kingdom.

The Committee recommends, therefore, that the Ministry of Supply be reminded of the urgent need for synthetic phenol, and that ample benzene and sulphuric acid are available in Scotland for the purpose. The supply of toluene is also adequate, and the sulphonation process is regarded as more attractive. Royal ordnance explosives factories in the west of Scotland appear to offer the most convenient sites for the manufacture of these phenols, and the Committee also recommends that the Director of Ordnance Factories should be informed accordingly. The Tar Research Association should be invited to explore methods for efficient recovery of such products as *o*-xylene and naphthalene for phthalic anhydride manufacture, and the Ministry of Supply should also be asked to consider the possibility of manufacturing methyl alcohol in Scotland as soon as the fertilizer situation is relieved.

The increasing use of plastics of the polyvinyl chloride, methacrylate and other types focuses attention on the unsaturated gases, acetylene and ethylene. The oil-refining and shale-oil industries could produce large volumes of ethylene and propylene in plant now available in Scotland, and the Committee accordingly recommends that the plastics and chemical industries should be advised that adequate amounts of unsaturated gases of the required purity for the manufacture of plastics and of antiseptics, insecticides, detergents and synthetic rubbers could be made available from the petroleum-refining and shale-oil industries and from coal carbonization in Scotland. Ethylene could also be recovered from coke-oven gas without seriously affecting the calorific value of the gas for most industrial purposes, and the Committee recommends that the coke manufacturers be encouraged to investigate this possibility.

Since five per cent of the estimated power of the hydro-electric schemes set apart for calcium carbide manufacture would make a substantial contribution to the needs of the plastics industry in Scotland for acetylene, it is recommended finally that the Secretary of State be informed of the urgent need of an established carbide industry in Scotland for chemical as well as engineering purposes. The Committee concludes by pointing out that the rapidly increasing developments in the manufacture of flexible plastic materials emphasizes the need for a wide range of suitable plasticizers, none of which is at present made in Scotland.

The economic aspects of the whole situation are not discussed in this report; this may well draw serious criticism from the economists for neglect of an essential factor.

THE NATIONAL FOUNDATION FOR ADULT EDUCATION

THE National Foundation for Adult Education has now been constituted since January 1947 and, besides its quarterly bulletin, *Foundation Papers*, has published various supplements dealing with subjects of immediate importance to its corporate members.

One supplement, "Voluntary Agencies in Adult Education", contains a summary of the aims and activities of voluntary bodies working in the field of adult education. Since there is no up-to-date and comprehensive directory of adult education, the information contained in this supplement should be of particular use to local education authorities in coming to grips with the development plans for further education which they have been asked to prepare. "Voluntary Agencies in Adult Education" will also be useful as a reference for individuals who are interested in various aspects of adult education. The supplement contains no reference to the work of university extra-mural departments and tutorial class committees, and it is intended that these should be considered in a later supplement.

The second supplement, called "Sources of Visual Aid Material: For use in the Adult Teaching of History and Contemporary Affairs", has been compiled by the deputy director, Extra-Mural Department, University of Manchester. The information has been collected partly at the request of the Association of Tutors in Adult Education and partly to meet the needs of tutors of the Manchester University Extra-Mural Department. It should also be useful to leaders of discussion groups and others concerned with adult education classes. The booklet contains a list of maps and charts, films, filmstrips, lantern slides and other pictorial material which would be suitable for adult classes of a general historical and geographical nature, and also a list of material suitable for teachers dealing with particular periods and countries.

Another supplement, "Accommodation for Adult Education: Some Examples and Suggestions", discusses an issue which presents difficulties to all the co-operating parties in adult education. A recent pamphlet of the Ministry of Education stated that: "Up and down the country there are a few colleges for further education which are housed in worthy buildings of dignity and beauty. But these are oases in the desert. For the most part there is a great dearth of educational accommodation of every kind from college to village hall, and further education, whether formal or informal, full-time or part-time, has at present to contend with most unsuitable premises." The National Foundation for Adult Education began in 1947 to collect information about the present availability of accommodation, and in this pamphlet it has brought together examples of improvisation at various levels, together with examples of more permanent provision. A short directory of the new short-term residential accommodation has also been included.

---

* Final Report of the Committee on Plastics: Plastics in Scotland. Pp. 16. (Edinburgh: Scottish Council (Development and Industry), 20 George Street, 1948.) 2*s*.

Because the literature about them is both brief and, in the main, out of date, some notes are included on the Cambridgeshire village colleges. These are one of the few working examples of combined educational provision, a subject which is being discussed in some detail to-day by the majority of local education authorities. The pamphlet should be useful in stimulating local education authorities and voluntary organisations to make a more searching examination of local possibilities for making more premises 'inter-available'. T. H. Hawkins

FORTHCOMING EVENTS

Tuesday, December 28

Royal Institution (at 21 Albemarle Street, London, W.1), at 3 p.m.—Sir Frederic Bartlett, F.R.S.: "The Mind at Work and at Play—Experiments in Psychology".

(Further Lectures on December 30, January 1, 4, 6 and 8.)

Wednesday, December 29

Royal Geographical Society (at Kensington Gore, London, S.W.7), at 2.30 p.m.—Mr. James Fisher and Dr. Ludwig Koch: "Exploring Britain's Islands". (Christmas Meeting for Young People.)

Thursday, December 30

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 3 p.m.—Mr. J. Melville: "Big Ships and their Docks—1, Building Big Ships". (Christmas Lectures to Boys.)

(Further Lectures on Monday, January 3, and Tuesday, January 4.)

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Senior Research Officer, and Research Officers (3), in the Pasture Research Division of the Department of Agriculture and Lands, Southern Rhodesia—The Secretary to the High Commissioner for Southern Rhodesia, Rhodesia House, 429 Strand, London, W.C.2 (December 31).

Scientists (with University qualifications in one or more of the subjects of physics, chemistry, zoology, engineering, botany, agriculture, physiology and hygiene) as assistants to the Director (Science), Festival of Britain 1951—The Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.321/48A (December 31).

Lecturer in the Electrical Engineering Department—The Clerk to the Governors, Woolwich Polytechnic, Woolwich, London, S.E.18 (January 1).

Research Fellowship in the Department of Chemical Engineering and Applied Chemistry—The Secretary, Imperial College of Science and Technology, South Kensington, London, S.W.7 (January 1).

Engineer II (unestablished) at a Ministry of Supply Research and Development Establishment, to take charge of experimental work in testing explosives and demolition equipment, etc.—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting E.569/48 (January 7).

Physical Chemist to take part in an investigation of tissue proteins and related problems—The House Governor and Secretary, Royal Cancer Hospital, Fulham Road, London, S.W.3 (January 11).

Professor of Astronomy—The Dean, Faculty of Science, Fouad I University, Cairo, Egypt (January 15).

Graduate with research experience in Organic Chemistry, for micro-analytical work, including teaching and research—The Registrar, The University, Liverpool (January 15).

Senior Lecturer or Lecturer in Anatomy—The Registrar, The University, Sheffield (January 22).

Chair of Philosophy in the University of Bern—Die Kantonale Erziehungsdirektion, Münsterplatz 3a, Bern, Switzerland (January 31).

Director of Research of the Australian Leather Research Association, Sydney—Mr. A. Harvey, Craigieburn, Duppas Hill Road, Croydon, Surrey.

Botanist in the East African Tsetse Reclamation Department, Kenya—The Director of Recruitment, Colonial Service, Colonial Office, Great Smith Street, London, S.W.1.

Honours B.Sc. Physicist for Radiotherapy Department—The Administrative Officer, Royal Berkshire Hospital, Reading, endorsed 'Appointment of Physicist'.

Entomologists (2) in the Department of Agriculture, Kenya—The Director of Recruitment, Colonial Service, Colonial Office, Great Smith Street, London, S.W.1.

Soil Survey Officers (3) in the Gold Coast to supervise the collection of information about the soils of the forest region in that territory—The Director of Recruitment, Colonial Service, Colonial Office, Great Smith Street, London, S.W.1.

Biochemist to the Reading Group of Hospitals—The Administrative Officer, Royal Berkshire Hospital, Reading, endorsed 'Appointment of Biochemist'.

Junior Graduate for biochemical work at Elstree, Herts—The Secretary, Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W.1.

Cerealist for the Directorate-General of Agriculture, Government of Iraq—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.N.18187/3C.

Physicist to investigate physical properties of dairy products, especially liquid milk—The Secretary, National Institute for Research in Dairying, Shinfield, Reading.

Assistant Engineer or Technician to assist in the maintenance of several 200-kilovolt X-ray installations—The Secretary, Mount Vernon Hospital and the Radium Institute, Northwood, Middx.

Physicist (preferably with some research experience) to study rheological properties of yarns and filaments—The Secretary, British Rayon Research Association, Bridgewater House, 58 Whitworth Street, Manchester 1.

Technician, (Grade II) in the Department of Civil Engineering—The Secretary, University College, Gower Street, London, W.C.1, quoting 'Civil Engineering/1'.

Chair of Zoology—The Registrar, The University, Nottingham.
